Abstract. We present an estimation of the uptake coefficient (γ) and yield of nitryl chloride (ClNO₂) (f) for the heterogeneous processing of dinitrogen pentoxide (N₂O₅) using simultaneous measurements of particle and trace gas composition at a semi-rural, non-coastal, mountain site in the summer of 2011. The yield of ClNO₂ varied between (0.035 ± 0.027) and (1.38 ± 0.60) with a campaign average of (0.49 ± 0.35). The large variability in f reflects the highly variable chloride content of particles at the site. Uptake coefficients were also highly variable with minimum, maximum and average γ values of 0.004, 0.11 and 0.028 ± 0.029, respectively, with no significant correlation with particle composition, but a weak dependence on relative humidity. The uptake coefficients obtained are compared to existing parameterizations based on laboratory datasets and with other values obtained by analysis of field data.

1 Introduction

The reaction of N₂O₅ with atmospheric aerosol represents an important nocturnal control on the atmospheric lifetime of NO_x and can impact the production of atmospheric oxidants, such as ozone and hydroxyl radicals (Dentener and Crutzen, 1993; Riemer et al., 2003; Brown et al., 2006; Macintyre and Evans, 2010). The reaction, in addition to loss of NO_x, results in the formation of particulate nitrate and can result in the release of ClNO₂ in both marine and continental environments (Osthoff et al., 2008; Kercher et al., 2009; Thornton et

al., 2010; Mielke et al., 2011; Phillips et al., 2012; Riedel et al., 2012a; Bannan et al., 2015).

Neglecting gas-phase diffusive effects, which are insignificant for transport of N₂O₅ to the submicron diameter particles dealt with in this study, the rate of loss of N₂O₅ on a particle surface can be described by the following expression:

$$\frac{d[\text{N}_2\text{O}_5]}{dt} = -0.25\bar{c}\gamma A [\text{N}_2\text{O}_5], \quad (1)$$

where \bar{c} is the mean molecular speed of N₂O₅, γ is the uptake coefficient, and A is the aerosol surface area density (i.e. the particle surface area per volume of air). This expression is the basis of the numerous laboratory studies designed to derive γ for tropospheric and stratospheric particles and their dependence on environmental variables such as temperature and relative humidity (Ammann et al., 2013).

The reaction of N₂O₅ with aqueous particles is complex. Following bulk accommodation, the uptake proceeds via disproportionation of N₂O₅ in the aqueous phase (Mozurkewich and Calvert, 1988) to form HNO₃ (and NO₃⁻):

In the presence of chloride, ClNO₂ can also be formed (Finlayson-Pitts et al., 1989; George et al., 1994; Behnke et al., 1997).

The relative rate of formation of the NO₃⁻ (or HNO₃) and ClNO₂ products of Reactions (R2) and (R4) depends on the fate of H₂NO₃⁺ (hydrated nitronium ion), thus on the concentration of chloride available (Behnke et al., 1997; Schweitzer et al., 1998; Thornton and Abbatt, 2005; Bertram and Thornton, 2009; Roberts et al., 2009) and on the rate coefficients for its aqueous phase reaction with Cl⁻ (*k*₄) or H₂O (*k*₂).

We define the branching ratio to ClNO₂ formation as *f* so that the net yield of NO₃⁻ and ClNO₂ formed (per N₂O₅ taken up) can be written as follows:

f can be calculated from knowledge of the relative chloride and water content of a particle and the rate coefficients *k*₂ and *k*₄:

$$f = \frac{k_4[\text{Cl}^-]}{k_4[\text{Cl}^-] + k_2[\text{H}_2\text{O}]}. \quad (2)$$

A value of *k*₄/*k*₂ of 450 is presently recommended (Ammann et al., 2013), but may be modified for systems with a significant concentration of aromatics which can also react with hydrated nitronium ions (Ryder et al., 2015).

Nitrate formed in the uptake of N₂O₅ can partition to the gas phase as nitric acid or remain in the particle depending on the pH, available ammonia/ammonium and temperature. Apart from highly acidic aerosol (Roberts et al., 2009) ClNO₂ is only weakly soluble/reactive and degasses completely from the particle. In the absence of appreciable chemical losses at night, ClNO₂ remains in the atmosphere until dawn when it is removed by photolysis over a period of a few hours (Ghosh et al., 2012).

The photochemical destruction of ClNO₂ recycles NO_x and activates Cl atoms for possible oxidation of VOCs, which may lead (via peroxy radical formation) to enhanced NO to NO₂ oxidation and ozone production (Simon et al., 2009; Sarwar et al., 2012). The chemical processes involved in the night-time formation of N₂O₅, its heterogeneous processing and the subsequent daytime photochemical reactions involving Cl atoms (and their impact on VOC oxidation and ozone formation) are illustrated in Fig. 1.

Laboratory studies (using synthetic surrogates for atmospheric aerosol) indicate that N₂O₅ uptake coefficients on aqueous, tropospheric aerosol are large (e.g. 1–3 × 10⁻² for

Figure 1. Gas- and aqueous-phase chemical processes forming ClNO₂ and particulate nitrate indicating the role of ClNO₂ in modifying the effect of N₂O₅ uptake on the chemical lifetime of NO_x and photochemical RO₂ generation.

ammonium sulfate) and show a complex dependence on environmental variables such as temperature and relative humidity as well as on the nitrate and chloride content of the particle. A detailed summary of the results of the laboratory studies is given by Amman et al. (2013).

Briefly, the presence of particulate nitrate has been seen to reduce γ , which is understood in terms of enhancing the rate of Reaction (R1b) compared to Reactions (R2a) and (R4) (Wahner et al., 1998a, b; Mentel et al., 1999; Hallquist et al., 2003; Bertram and Thornton, 2009). In contrast, the presence of chloride increases γ through the competitive removal of H₂NO₃⁺ in Reaction (R4) (Bertram and Thornton, 2009). Laboratory experiments have also documented the reduction of γ caused by particle phase organics, including organic coatings, which lower the water activity and the hydrolysis rate of N₂O₅ and possibly the rate of accommodation of N₂O₅ at the gas–particle interface (Anttila et al., 2006; Badger et al., 2006; McNeill et al., 2006; Park et al., 2007; Cosman and Bertram, 2008; Cosman et al., 2008; Gaston et al., 2014). The uptake coefficient to dry particles is reduced for the same potential reasons (Hu and Abbatt, 1997; Thornton et al., 2003).

The loss of N₂O₅ to ambient aerosol samples (as opposed to chemically simpler aerosol surrogates prepared in the laboratory) was investigated by Bertram and colleagues (Bertram et al., 2009a, b; Riedel et al., 2012b) who generated gas-phase N₂O₅ and monitored its loss via uptake to atmospheric aerosol sampled into a flow reactor. The results indi-

cated that the uptake coefficient was highly variable, sometimes approaching a factor of 10 lower than derived from laboratory studies using synthetic aerosol and strongly dependent on aerosol composition, especially the water/organic content. Other, less direct measurements of N₂O₅ reactivity on ambient particles (discussed in detail later) indicate high variability and occasional low values that are inconsistent with laboratory investigations on pure samples.

In this paper we address the need for measurements of the N₂O₅ uptake coefficient to particles in the real atmospheric environment. We present simultaneous measurements of particle composition, N₂O₅ and ClNO₂ to derive both the uptake coefficient (γ) and the efficiency (f) of ClNO₂ production in a number of different air masses and discuss the limitations and validity of this and similar approaches.

2 Methods

2.1 PARADE field site

The PARADE measurement intensive campaign (PARTicles and RADicals: Diel observations of the impact of urban and biogenic Emissions) took place between mid-August to mid-September 2011 at the Taunus Observatory (TO), Kleiner Feldberg, Germany. The observatory is operated by the Institute for Atmospheric and Environmental Science of the Goethe University, Frankfurt. The Kleiner Feldberg (825 m above sea level) sits within the Taunus range approximately 30 km NW of Frankfurt am Main, Germany. The site, which may be described as rural with anthropogenic impact from local industrial/population centres, is described in more detail by Wobrock et al. (1994), Handisides (2001), Crowley et al. (2010) and Sobanski et al. (2016). It is \approx 400 km away from the nearest (North Sea) coastline.

2.2 Instrumentation

N₂O₅ and NO₃ were measured using cavity ring-down spectroscopy (CRDS) with instruments described by Schuster et al. (2009) and Crowley et al. (2010). NO₃ was measured directly in a cavity at ambient temperature whereas the sum N₂O₅ + NO₃ was measured in a separate cavity at \sim 100 °C after thermal decomposition of N₂O₅ to NO₃ in a heated section of the inlet, also at 100 °C. Following corrections for the transmission of NO₃ and N₂O₅ through the inlets, filter and cavities, the difference signal is used to calculate N₂O₅ mixing ratios.

The CRDS was situated on a platform on the roof of the TO laboratory at a height of 10 m from the ground. Air was drawn through a 1 m length of 1/2 inch (12.7 mm) outer diameter Teflon (perfluoroalkoxy, PFA) tubing at 50 standard L min⁻¹ (SLM) and sampled (18 SLM) from the centre of the flow via 1/2 inch (6.35 mm) PFA tubing and a Teflon filter (exchanged hourly using an automatic filter changer) into the two cavities of the CRDS. This set-up keeps

inlet residence times short (\sim 0.1 s) and reduces sampling of coarse particles and droplets. The total uncertainty associated with the N₂O₅ measurements was 15 % with the largest contribution from the uncertainty in the NO₃ cross section and NO₃ losses.

The non-refractory composition of particulate matter with an aerodynamic diameter less than 1 μ m (PM₁) was measured with an Aerodyne HR-ToF aerosol mass spectrometer (AMS) (Jayne et al., 2000; DeCarlo et al., 2006). The AMS was deployed on board the MPIC mobile laboratory (MoLa) (Drewnick et al., 2012) located approximately 15 m from the measurement station with air sampled from \sim 7 m above the ground via wide bore metal tubing at a flow rate of 90 (SD) L min⁻¹. Total organic, nitrate, sulfate and chloride in non-refractory particles of < 1 μ m diameter (NR-PM₁) are reported here. As the AMS detects marine chloride (i.e. refractory chloride) with 1 to 2 orders of magnitude lower sensitivity than non-refractory chloride (Zorn et al., 2008; Ovadnevaite et al., 2012; Schmale et al., 2013; Drewnick et al., 2015) it is reasonable to assume that the majority of the Cl⁻ reported by the AMS is due to NH₄Cl arising from uptake of gas-phase HCl which may have marine or anthropogenic origin. The AMS was calibrated using the measurement of standard ammonium nitrate particles of known particle size via a differential mobility analyser.

Particle size spectra were measured using an optical particle counter (OPC, Model 1.109, Grimm), an aerodynamic particle sizer (APS, Model 3321, TSI) and a fast mobility particle size spectrometer (FMPS, Model 3091, TSI). All particles were sampled at ambient RH so corrections for hygroscopic particle growth were not necessary. The uncertainties associated with parameters required for calculation of the uptake coefficient are 25 % for the nitrate measurement and 30 % for the particle diameter measurement (Wiedensohler et al., 2012). Note that an uncertainty in the particle diameter of \sim 30 % implies an uncertainty in the particle surface area of \sim 70 %. This uncertainty applies not only to this study, but also to all previous laboratory and field studies that use similar instrumentation, thus a certain cancelling of errors occurs when comparing it to other datasets.

NO₂ was measured during PARADE using a variety of techniques which all showed good agreement. The data used in this analysis were obtained using the MPIC NO₂ TD-CRDS system (Thieser et al., 2016). The instrument is a two-cavity system which also measured total peroxy nitrates and total alkyl nitrates (Σ PNs and Σ ANs). The atmosphere was sampled by drawing air at \sim 20 SLM through a 3/8 inch (\sim 9.5 mm) outer-diameter PFA tube 8 m in length and sub sampling approximately 4 SLM into the cavity. The main inlet was shared by the iodide CIMS system which was used to measure ClNO₂, speciated peroxy nitrates and peroxy acids (Phillips et al., 2012, 2013b).

The ClNO₂ dataset and method was described by Phillips et al. (2012) and follows prior measurements of ClNO₂ using the same technique (Osthoff et al., 2008; Thornton et al.,

2010; Mielke et al., 2011). The CIMS instrument was constructed by THS Instruments, Georgia, USA and is based on the CIMS technique described by Slusher et al. (2004) and Zheng et al. (2011). No indication of the production of $ClNO_2$ on the inlet walls was observed. $ClNO_2$ was monitored at $I^{37}Cl^-$ ($m/z = 163.9$, with a LOD (2σ) of 12 pptv) for the entire period; however there are clear indications (i.e. non-zero daytime concentrations) that the signal at this mass is not solely due to $ClNO_2$; consequently $IClNO_2^-$ ($m/z = 207.9$) was monitored with a LOD (2σ) of 3 pptv, from 2 September 2011. The impurity at $m/z = 163.9$ contains one chlorine atom ($m/z = 161.9$ was also observed at the correct isotope ratio) and has a diel cycle that strongly resembles that of HCl, which was measured using ion-chromatography during a subsequent campaign (Phillips et al., 2013a) at the same site and time of year. The mechanism of HCl detection at $m/z = 161.9$ and $m/z = 163.9$ remains unclear as the reaction $I^- + HCl \rightarrow ICl^- + H$ is endothermic by at least 200 kJ mol^{-1} .

The instrument sensitivity to $ClNO_2$ was determined by the measurement of a $ClNO_2$ standard synthesized by passing Cl_2 over a mixture of $NaNO_2$ and $NaCl$ crystals in a flow of humidified N_2 . The concentration of the standard was determined using thermal dissociation cavity ring-down absorption spectroscopy (TD-CRDS) using the instrument described by Thieser et al. (2016). A zero measurement, using a bypass with 25 cm of metal wool heated to 473 K, was made once an hour and the accuracy of the $ClNO_2$ measurement is 25 % (Phillips et al., 2012).

Meteorological data were obtained from the public data depository of the Hessisches Landesamt für Umwelt und Geologie (HLUG) monitoring station situated at the peak of the Kleiner Feldberg approximately 10 m from the main sample inlet location. Data is available from <http://www.hlug.de/start/luft/luftmessnetz.html>. Back-trajectories were calculated using HYSPLIT (Hybrid Single Particle Lagrangian Integrated Trajectory Model) (Draxler and Rolph, 2011; Stein et al., 2015).

3 Meteorological/chemical conditions during PARADE

The time series of a selection of particle and trace-gas concentrations measured during PARADE is shown in Figs. 2 and 3 along with temperature and relative humidity.

3.1 Particle characteristics

Figure 2 indicates that the aerosol surface area (A) available for uptake of N_2O_5 was highly variable and was predominantly (> 75 % on average) associated with particles less than 550 nm in diameter (FMPS data). Relative humidity, an environmental parameter which influences the water content of the particles and is thus expected to influence the uptake of N_2O_5 significantly, varied between 25 and 100 %. On av-

Figure 2. Time series of temperature, relative humidity and particle properties during PARADE. A is aerosol surface area. Non-refractory, PM₁ organic, nitrate, sulfate and ammonium were measured by the AMS. Aerosol surface area was measured by an FMPS (20–500 nm) and by APS (> 0.5 μm) and OPC (> 0.25 μm).

erage, the submicron non-refractory aerosol was (by mass) 55 % organic, 26 % sulfate and nitrate and ammonium were both 9.5 %, which may be considered typical for an anthropogenically influenced, rural region. Particulate sulfate and organic content were correlated, with the particulate sulfate-to-organic mass ratio, a parameter that potentially impacts on the N_2O_5 uptake to particles (Bertram et al., 2009b), varying between ~ 0.1 and 2.4 with a mean value of ~ 0.6 . The campaign-averaged nitrate particle mass concentration was $0.56 \mu\text{g m}^{-3}$ during the day and $0.89 \mu\text{g m}^{-3}$ during the night at this site. The larger night-time values reflect high rates of nitrate production from N_2O_5 uptake at night rather than temperature-dependent partitioning of HNO_3 / NH_3 / ammonium nitrate (Phillips et al., 2013a), which we discuss below.

3.2 NO_x , O_3 and N_2O_5 formation

As reported previously for this site (Crowley et al., 2010; Phillips et al., 2012; Sobanski et al., 2016) local emissions result in high variability in NO_x with NO_2 usually between ~ 0.5 and 10 ppbv but with excursions up to ~ 20 ppbv. Day-time maxima for NO were between ~ 0.5 and 2 ppb and

Figure 3. Time series of CINO₂ and its precursor, N₂O₅. Global radiation (yellow) is plotted to separate day-to-night periods and to indicate the day-to-day relative photochemical activity. The precursors to N₂O₅ (NO₂ and O₃) are shown as are the AMS measurement of particulate nitrate (as in Fig. 2) and chloride.

ozone levels were between 20 and 70 ppbv. The high variability in NO₂ and O₃ result in a highly variable NO₃ production term between <0.05 and >0.5 pptv s⁻¹ (Sobanski et al., 2016). The NO₃ and N₂O₅ lifetimes were also highly variable and on some nights (notably 20–21 and 30–31 August, 31 August–1 September, 1–2 September), on which extended NO₃ (and N₂O₅) lifetimes were observed, we have compelling evidence that the inlets were sampling from a relatively low-altitude residual layer (Sobanski et al., 2016).

3.3 Meteorology, CINO₂ and particulate nitrate

The PARADE measurement period began on 15 August and ran until 17 September. As described by Phillips et al. (Phillips et al., 2012), this period may be separated into three meteorologically distinct parts.

Period 1 (17–26 August) The period beginning on the 17 August and ending on 26 August was changeable with calculated air mass 24 h back-trajectories suggesting the air was largely continental in origin, arriving from the west-to-south wind sector. The exceptions to the continental origin occurred up to sunrise on 17 Au-

gust and on the 19–20 August with air arriving at the site with relatively high humidity from the NW, with 48 h back-trajectories indicating an approximate UK/English channel origin. On the nights of the 17–18 and 19–20 August, concurrent increases in CINO₂ and NR PM₁ NO₃⁻ were observed. There is little indication of nocturnal production of CINO₂ on the remaining nights of this initial period of the measurements. In fact, on the night of 20–21 August high concentrations of N₂O₅ were measured, [N₂O₅]_{max} ≈ 800 pptv, during a period of low RH of 25 % (lowest observed during the measurement period). No concurrent increase in the concentration of submicron particulate nitrate or CINO₂ was measured.

Period 2 (26–29 August) On the evening of 26 August a front passed across the measurement site associated with heavy cloud cover and rain. Before the passage of the front, large, variable concentrations of NO_x were measured, coinciding with an increase in PM₁ particle mass. The rain was sustained following the passing of the front and a RH of 100 % was measured into the morning of 28 August. After the front, concentrations of fine particles, as measured by the FMPS and AMS, and NO_x were relatively low and remained suppressed until 29 August, with the exception of NR PM₁ Cl⁻ which peaked on the nights of 27–28 and 28–29 August, possibly due to the marine influence of the post-frontal air and the increased supply of chloride from marine particles. Following 29 August, large concentrations of CINO₂ were observed on a series of nights up to and including 3 September. Back-trajectories calculated with the HYSPLIT model suggest that the westerly flow following the front gradually weakened and a surface high pressure set in leading to high concentrations of NO_x and O₃ probably due to the influence of the near conurbation of Frankfurt–Wiesbaden–Mainz.

Period 3 (29 August–9 September) The remainder of the measurement period was influenced by a mainly westerly flow and the observatory was frequently shrouded with cloud. Nocturnal production of modest concentrations of CINO₂ occurred between 6 September and 9 September without a concomitant increase in NR PM₁ NO₃⁻. Each of these overnight periods was impacted by cloud at the measurement site with the exception of the 6 September when the RH was nevertheless above 90 %. Measurements of particle composition during PARADE were only available at the submicron size; it may be possible that during misty and cloudy conditions the nitrate formation occurred on surfaces which were not measured, i.e. larger mist or fog droplets, and in some cases formed nitrate was scavenged within the clouds. Photolysis frequencies were attenuated by the cloud cover and rain at the site during this period, allowing measurable quantities of CINO₂ to persist well past noon, see for

example 8 to 9 September. N₂O₅ was not measured beyond 9 September; however, the small amount of data available during this period suggests that relative productivity with respect to ClNO₂ was high.

4 Estimation of f and γ for N₂O₅ uptake to ambient aerosol

Apart from the measurement of the loss rate of synthetic N₂O₅ samples to ambient aerosol as carried out by Bertram and colleagues (see Sect. 1), there are different methods by which ambient measurements can be analysed to derive an uptake coefficient (γ) for N₂O₅ interaction with atmospheric particles, which depend on the data available. These include (1) the analysis of product formation (gas and/or particle phase) resulting from the uptake of N₂O₅ (Mielke et al., 2013), (2) analysis of the steady-state N₂O₅ (or NO₃) lifetime (Brown et al., 2006, 2009, 2016a) and (3) box modelling of N₂O₅ chemistry with various observational constraints (Wagner et al., 2013). All three methods have their own strengths and weaknesses and all contain assumptions that are evidently not applicable in all cases.

We first discuss the methods which we have applied (1 and 2) to derive f and γ during the PARADE measurement campaign and compare the results to similar analyses in the literature.

4.1 Method 1: using product formation rates to derive f and γ

For the PARADE campaign, periods of data were identified where clear correlations between particulate nitrate and ClNO₂ were observed, as illustrated, for example, in Fig. 4. On these nights, there is no particulate nitrate formation without concurrent ClNO₂ formation and the covariance of NO₃⁻ and ClNO₂ is taken as evidence that, to a good approximation, both ClNO₂ and particulate nitrate are produced only by the uptake of N₂O₅.

From Eq. (1) and the definition of the branching ratio (Reaction R5), the rate of production of ClNO₂ ($p\text{ClNO}_2$) from the reaction of N₂O₅ with aerosol (surface area A) can be written as follows:

$$p\text{ClNO}_2 = \frac{d[\text{ClNO}_2]}{dt} = f(0.25\gamma\bar{c}A[\text{N}_2\text{O}_5]). \quad (3)$$

The rate of production of particulate nitrate ($p\text{NO}_3^-$) is

$$p\text{NO}_3^- = \frac{d[\text{NO}_3^-]}{dt} = 2(1-f)(0.25\gamma\bar{c}A[\text{N}_2\text{O}_5]) + f(0.25\gamma\bar{c}A[\text{N}_2\text{O}_5]). \quad (4)$$

Combining and rearranging Eqs. (3) and (4) we get

$$f = 2\left(\frac{p\text{NO}_3^-}{p\text{ClNO}_2} + 1\right)^{-1} \quad (5)$$

and

$$\gamma = \frac{2(p\text{ClNO}_2 + p\text{NO}_3^-)}{\bar{c}A[\text{N}_2\text{O}_5]} \quad (6)$$

Note that the fractional formation of ClNO₂ (f) is the amount of ClNO₂ formed per N₂O₅ taken up to a particle and should not be confused with the yields of ClNO₂ per NO₃ formed that have occasionally been reported (Osthoff et al., 2008; Mielke et al., 2013) and represent lower limits to f as NO₃ is not necessarily converted stoichiometrically to N₂O₅ in the atmosphere.

Equation (5) illustrates that measurement of the production rates of ClNO₂ and particulate nitrate is sufficient to derive the fractional yield of ClNO₂ (f) and that, by also measuring the concentrations of N₂O₅ and aerosol surface area (A), we can derive the uptake coefficient, γ (Eq. 6). Note that without measurement of both particulate nitrate and ClNO₂ production, it is not possible to derive both the yield of ClNO₂ and the uptake coefficient. By analysing the ClNO₂ product alone, Eq. (3) can be used to derive a composite term ($\gamma \times f$) as described by Mielke et al. (2013).

The analysis assumes that, during the period over which data are analysed, the relevant properties of the air mass are conserved and the losses of either measured species are not significant. It also assumes that the efficiency of N₂O₅ uptake and ClNO₂/NO₃⁻ production is independent of particle size. Later we examine the effect of considering uptake to coarse and fine aerosol particles separately as previously done by Mielke et al. (2013). Two further assumptions are 1) that measurement of $p\text{NO}_3^-$ accounts for the total production of nitrate by Reaction (R3); i.e. NO₃⁻ formed from uptake of N₂O₅ does not significantly degas from the particle as HNO₃, and 2) the formation of particulate nitrate via the net uptake of HNO₃ to aerosol as the temperature drops at the night is insignificant compared to that formed in N₂O₅ uptake. Note that the degassing of NO₃⁻ as HNO₃ will result in an underestimation of γ , and overestimation of f , whereas the net uptake of HNO₃ (forming particulate nitrate) will have the opposite effect.

Regarding assumption (1) we note that the increase of particulate nitrate at night is accompanied by an equivalent increase in ammonium (see Fig. 4) as gas-phase ammonia repartitions to form ammonium nitrate and buffers the release of HNO₃. For a given ammonia concentration, as the temperatures fall during night-time, the partitioning increasingly favours the retention of particulate nitrate over release of HNO₃. During a subsequent campaign at this site, we showed that the night-time formation of particulate nitrate is dominated by N₂O₅ uptake (Phillips et al., 2013a). We also showed that, once corrected for the contribution of N₂O₅, the measurements of gas-phase HNO₃ did not reveal night-time increases coincident with those of particulate nitrate, suggesting that N₂O₅ uptake is not an important source of HNO₃ at this site. This is likely to be related to the cool nights at altitude of > 800 m and the abundance of ammonia in this mixed ru-

Figure 4. Zoomed-in graph of particle-nitrate and ClNO₂ formation over 4 nights. Global radiation (yellow) is plotted to separate day-to-night periods and indicate the day-to-day relative photochemical activity. Note that the ClNO₂ plotted for these days was measured at $m/z = 161.9$ and, therefore, contains a contribution from HCl, hence the apparent daytime production.

ral/industrialized region of Germany. Additionally, the strong temperature dependence of partitioning between ammonia, HNO₃ and ammonium nitrate would result in a bias towards high values of γ at low temperatures which prevent release of nitrate from the particles. The uptake coefficients obtained in this study showed no significant dependence on temperature (see below).

Regarding assumption (2) we note that the strong correlation observed between ClNO₂ and NO₃⁻ concentrations is a useful indicator that the source of particulate nitrate is dominated by N₂O₅ uptake and not HNO₃ uptake as N₂O₅ and HNO₃ have completely different diel profiles and atmospheric lifetimes.

Three different types of analysis were used to derive uptake coefficients and the fractional formation of ClNO₂. In the simplest method (1a) to derive f we use longer time periods (several hours or the whole night) where plots of [ClNO₂] and [NO₃⁻] are approximately linear and values of f are estimated from a linear fit of the data as exemplified in

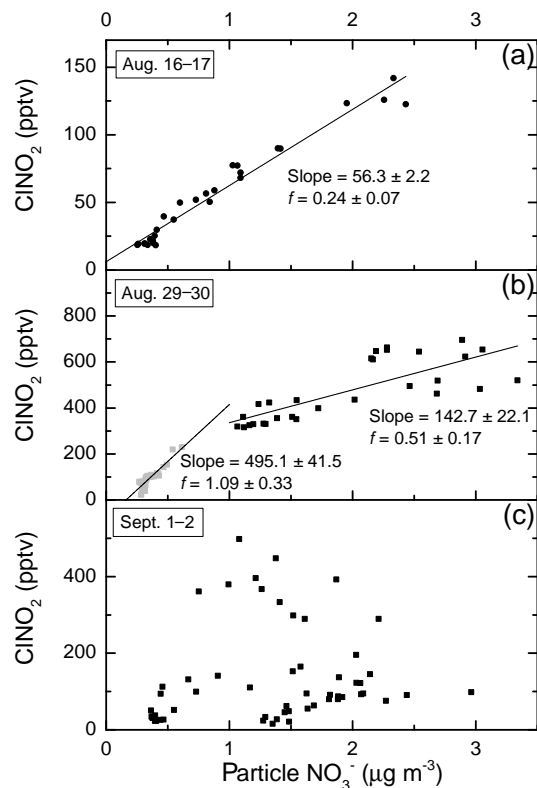

Figure 5. Plots of ClNO₂ and NO₃⁻ for three different campaign nights. The slopes are converted to a fractional formation of ClNO₂ (f) via Eq. (5).

Fig. 5. On some nights (four in total) a linear relation is observed (Fig. 5a) whereas air mass changes can result in two distinct slopes (Fig. 5b, 2 nights in total) or such variability that analysis over a prolonged period is impossible (Fig. 5c, all other nights). For the example displayed in Fig. 5a, a slope of $56.3 \pm 2.2 \text{ pptv } \mu\text{g}^{-1} \text{ m}^3$ (2σ statistical error) results in a value of $f = 0.24 \pm 0.07$, where the error in f includes overall uncertainty in the measurement of ClNO₂ and NO₃. Using this method, a total of 8 values of f were obtained during the campaign.

In order to derive γ , absolute production rates of NO₃⁻ and ClNO₂ are required and in method 1b shorter periods of data, usually between 1 and 3 h, were chosen by inspection of the time series such that NO₃⁻ and ClNO₂ concentrations both increase during a period of relatively constant composition and environmental variables, such as temperature and RH. It is more likely that the assumptions hold during the shorter time periods chosen for 1b than the longer sections of data used in 1a. In this case, values of $p\text{ClNO}_2$ and $p\text{NO}_3^-$ and average values of A and [N₂O₅] are calculated for the same period and inserted into Eqs. (5) and (6) to derive f and γ . An example of this analysis is shown in Fig. 6, which indicates (grey shaded area) time periods in which ClNO₂ and NO₃⁻ concentrations increased while other parameters (e.g. N₂O₅,

Figure 6. Plot demonstrating the derivation of f and γ from ClNO_2 and NO_3^- measurements using analysis method 1b. The grey area represents the time period in which $p\text{ClNO}_2$ and $p\text{NO}_3^-$ were measured. Average values of RH, $[\text{N}_2\text{O}_5]$ and A over the same period are also indicated.

A and RH) were relatively constant. In this example between $\sim 21:00$ and $23:20$ on the night 29–30 August, values of $p\text{ClNO}_2$ ($14.6 \pm 3.0 \text{ pptv h}^{-1}$), $p\text{NO}_3^-$ ($21.0 \pm 5.1 \text{ pptv h}^{-1}$), \bar{A} (7.6 ± 2.2) $\times 10^{-7} \text{ cm}^2 \text{ cm}^{-3}$, $[\text{N}_2\text{O}_5]$ ($153 \pm 43 \text{ pptv}$) were obtained. The uncertainties quoted were derived by propagating statistical uncertainty (e.g. in the production rate of ClNO_2 from fitting to the data) and absolute uncertainty in the measurements of the concentrations of ClNO_2 , N_2O_5 , particulate nitrate and aerosol surface area as listed in Sect. 2.2. Generally, the absolute error in the concentration measurements dominates the overall uncertainty for each parameter, the major exception being N_2O_5 , which could be sufficiently variable over the averaging period for it to also contribute significantly. Inserting this set of parameters into Eqs. (5) and (6) results in $f = (0.82 \pm 0.26)$ and $\gamma = (7.3 \pm 3.1) \times 10^{-3}$ at $\text{RH} = 77 \pm 2 \%$ and a temperature of $8 \pm 1 \text{ }^\circ\text{C}$. Using this method a total of 12 values of γ were obtained during the campaign.

A more rigorous analysis, which avoids use of average values of A and $[\text{N}_2\text{O}_5]$ was also carried out. In this case $p\text{NO}_3^-$ and $p\text{ClNO}_2$ are calculated from 10 min averaged datasets

Figure 7. Plot demonstrating the derivation of f and γ from ClNO_2 and NO_3^- measurements using analysis method 1c. The red lines are the predicted, integrated concentrations of NO_3^- and ClNO_2 calculated using the summed particle surface area (A) from both coarse and fine particles. In this particular case, the analysis returns a value of $\gamma = 0.085$ and $f = 0.33$. The relative humidity over this period was $82 \pm 2 \%$.

using the right-hand sides of Eqs. (3) and (4) respectively, taking measured values of N_2O_5 and A at each time step and using an initial estimate for f and γ . The predicted concentrations of ClNO_2 and NO_3^- were then calculated for each time step by integration over the analysis time period. Values of f and γ were then varied and the integration repeated until good agreement between observed and calculated $[\text{ClNO}_2]$ and $[\text{NO}_3^-]$ was obtained. An example of this type of analysis (for the night 19–20 August) is displayed in Fig. 7. The red lines are the results of the analysis in which the total particle surface area was used. Later, we discuss the effects of separately calculating the formation of NO_3^- and ClNO_2 from the fine and coarse aerosol fractions. Unlike method 1b, a limitation of this procedure is that the analysis is limited to the first period of the night. Similarly to method 1b, it cannot predict negative changes in concentrations of ClNO_2 or NO_3^- which are a result of changes in air mass origin/age.

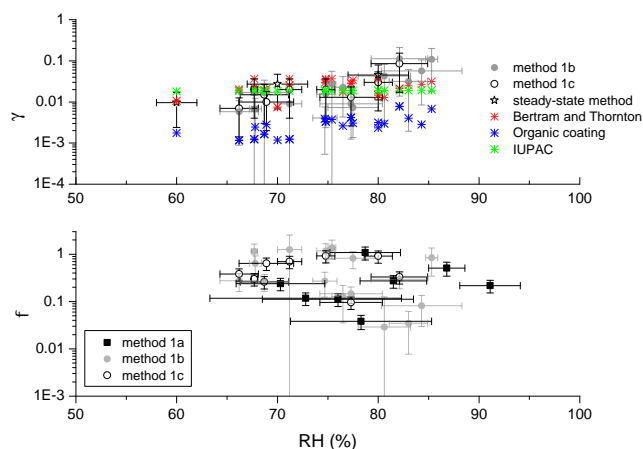

Figure 8. Values of γ and f derived via methods 1a–1c and the steady-state analysis during PARADE. The vertical error bars represent total uncertainty including errors associated with the measurement of concentrations of trace gases and particle surface areas. The horizontal error bars are the standard deviation of the relative humidity over the measurement period (1–3 h for methods 1b and 1c and up to 8 h for method 1a). The red stars represent uptake coefficients calculated using the Bertram and Thornton (2009) parameterization, the blue stars include the impact of an organic coating (Anttila et al., 2006).

The values of f and γ derived from methods 1a–1c are plotted against RH in Fig. 8. The data are colour coded according to the method used.

The lower panel of Fig. 8 reveals high variability in the values of f obtained, which range from 0.035 ± 0.027 to 1.38 ± 0.60 . The errors on each individual determination vary from ~ 35 to $\sim 100\%$, which is the result of scatter in the data as well as uncertainty associated with measurements of ClNO₂ and particle-NO₃[−] and can result in non-physical values larger than unity. A further possible reason for values of f that exceed unity is the degassing of NO₃[−] as HNO₃ from the particles, though as described above, this effect is expected to be small.

The average value of γ obtained for the campaign considering both methods 1b and 1c was 0.027 with a standard deviation of 0.03. Minimum and maximum values were 0.004 and 0.11 respectively. The large standard deviation reflects the great variability in the values of γ obtained, with up to a factor of 10 difference in γ at the same relative humidity. Considering the large variability, the values of γ obtained using methods 1b and 1c over the same time period are in reasonable agreement with an average ratio of 1.7. We compare the values of γ obtained during PARADE with other ambient datasets below.

4.2 Method 2: NO₃ steady state lifetime analysis

Atmospheric N₂O₅ is formed in a series of oxidation steps initiated mainly by the reaction of NO₂ with O₃ (R7).

Ambient concentrations of NO₃ and N₂O₅ are thus coupled via the gas-phase, thermochemical equilibrium that exists due to Reactions (R8) and (R9), so that the relative amounts of NO₃ and N₂O₅ are determined by temperature and NO₂ levels.

The so-called “steady state” determination method for γ is based on the assumption that, after a certain period of time following sunset (often on the order of hours), the direct and indirect losses of NO₃ and N₂O₅ balance their production. The steady-state lifetimes can then be calculated from observations of the NO₃ and N₂O₅ concentrations and the production term $k_7[\text{NO}_2][\text{O}_3]$, where k_7 is the rate constant for Reaction (R7). This method was first used by Platt and colleagues to assess the heterogeneous loss of N₂O₅ (Platt and Heintz, 1994; Platt and Janssen, 1995; Heintz et al., 1996), and has been extended by Brown and colleagues to derive γ in regions far from NO_x sources such as the marine environment (Aldener et al., 2006), aloft (Brown et al., 2006; Brown et al., 2009) and most recently for the continental boundary layer (Brown et al., 2016a). [NO₂] and [O₃] measurements are required to calculate the rate of NO₃ production, which is generally assumed to be via Reaction (R7) only, although a contribution of NO₂ oxidation by stabilized Criegee intermediates has recently been hypothesized to represent a potential bias to this calculation (Sobanski et al., 2016). The steady-state analysis does not require any information about products formed by N₂O₅ heterogeneous reactions.

The inverse steady-state lifetimes of NO₃ (τ_{NO_3}) and N₂O₅ ($\tau_{\text{N}_2\text{O}_5}$) are given by expressions Eqs. (7) and (8) respectively:

$$(\tau_{\text{NO}_3})^{-1} \approx \gamma (0.25\bar{c}A K_{\text{eq}}[\text{NO}_2]) + k_g \quad (7)$$

$$(\tau_{\text{N}_2\text{O}_5})^{-1} \approx k_g (K_{\text{eq}}[\text{NO}_2])^{-1} + 0.25\bar{c}A\gamma \quad (8)$$

Where K_{eq} is the temperature-dependent equilibrium constant describing the relative concentrations of NO₂, NO₃ and N₂O₅ (Reactions R8 and R9), [NO₂] is the concentration of NO₂, and k_g is the pseudo first-order loss constant for NO₃ loss in gas-phase reactions (e.g. with NO or with hydrocarbons). A plot of $(\tau_{\text{NO}_3})^{-1}$ or $(\tau_{\text{N}_2\text{O}_5})^{-1} K_{\text{eq}}[\text{NO}_2]$ against $0.25\bar{c}A K_{\text{eq}}[\text{NO}_2]$ should be a straight line with γ as slope and k_g as intercept. This method thus relies on the fact that the relative concentrations of N₂O₅ and NO₃ vary with $K_{\text{eq}}[\text{NO}_2]$, thus the contribution of their individual losses to the overall lifetime of both NO₃ and N₂O₅ also varies with [NO₂] once changes in temperature (thus K_{eq}) are accounted

for. The method therefore assumes that, for a given analysis period in which NO₂ is changing sufficiently to change the relative loss rates of NO₃ and N₂O₅, both γ and k_g are constant (i.e. do not depend on [NO₂]). This will not always be the case and we have often observed that the relation between $(\tau_{\text{NO}_3})^{-1}$ and $K_{\text{eq}}[\text{NO}_2]$ is non-linear. In environments where NO₃ losses are dominated by gas-phase reactions of NO₃, the uncertainty associated with the derivation of γ via a steady-state analysis is clearly greatly enhanced.

Figure 9 illustrates some of these issues for data obtained over a period of several hours on the nights 1–2, 2–3 and 5–6 September. The first 2 nights (1–2 and 2–3 September) had long NO₃ lifetimes and were selected for analysis as long NO₃ lifetimes represent periods with low rates of NO₃ loss by gas-phase processes (i.e. k_g is small). We have previously shown (Sobanski et al., 2016) that the long NO₃ lifetimes on these nights result from sampling from a low-altitude residual layer. A large variability in the night-time NO₂ mixing ratio on these nights (~ 1 to 13 ppbv, see Fig. 9a and c) should result in a significant shift in the NO₂-to-N₂O₅ ratio, thus to the sensitivity in the NO₃ lifetime to the uptake of N₂O₅ to aerosol. On the night of 1–2 September, plume-like features in the NO₂ mixing ratio at $\sim 22:00$, 01:30 and 04:00 were accompanied by decreases in the steady-state NO₃ lifetime. The inverse NO₃ lifetime is plotted against $0.25\bar{c}A K_{\text{eq}}[\text{NO}_2]$ in Fig. 9b. Here we have selected data that was obtained from about 2 h after sunset to the next dawn when NO₃ started to decrease as represented by the red data points in Fig. 9a. The slope of the plot results in values of $\gamma = (9.6 \pm 0.7) \times 10^{-3}$ and $k_g = (2.0 \pm 0.6) \times 10^{-4} \text{ s}^{-1}$, where the errors are statistical only. Over the period analysed, the relative humidity (blue line in Fig. 9a) was $60 \pm 2\%$.

On the night 2–3 September at about 19:30 UTC (≈ 1 h after sunset), the NO₃ lifetime increases gradually to a value of ~ 900 s until 21:30 as NO₂ decreases from ~ 7 to 3 ppbv. A rapid increase in NO₂ at 21:30 is then accompanied by a much shorter NO₃ lifetime. After $\sim 22:00$, NO₂ slowly decreases and the NO₃ lifetime recovers to about 500 s. Thus, for this night there is also a clear anti-correlation between NO₂ and the NO₃ lifetime. Figure 9d plots the inverse of the NO₃ lifetime against $0.25\bar{c}A K_{\text{eq}}[\text{NO}_2]$ with the data point colour coded according to relative humidity. The first period of the night (orange, yellow and green data-points) are best described (black line) by an uptake coefficient of $(2.7 \pm 0.2) \times 10^{-2}$ and $k_g = (1.0 \pm 0.4) \times 10^{-4} \text{ s}^{-1}$. The second period (starting ~ 5 h after sunset) is best characterized by larger values of $\gamma = (4.5 \pm 0.3) \times 10^{-2}$ and $k_g = (1.5 \pm 0.1) \times 10^{-3} \text{ s}^{-1}$ (errors are statistical only). We note that prior to the peak in NO₂ at 21:30 the relative humidity of the air was stable at $\approx 70 \pm 3\%$ whereas after 22:00 it remained at $80 \pm 3\%$. A shift in air mass to one with larger water vapour content could help explain the larger values of γ obtained in the second period of this night and may also be the reason for the larger gas-phase losses of NO₃ if the more humidified air mass is more impacted by boundary

layer emissions. On two other nights when the NO₃ lifetimes were long (30–31 August and 31 August–1 September), there was very little variation in NO₂ so that the steady-state lifetime of NO₃ was insensitive to the uptake coefficient.

In Fig. 9e and f we present data that were obtained with sufficient variation in NO₂, but with relatively short NO₃ lifetimes. As in the datasets discussed above, NO₃ lifetimes are anti-correlated with NO₂. However, the plot of the inverse of the NO₃ lifetime against $0.25\bar{c}A K_{\text{eq}}[\text{NO}_2]$ in Fig. 9f has a very large slope, resulting in $\gamma \approx 0.3$ and a negative intercept. Unrealistically large values of γ and negative intercepts can be caused by a covariance between NO₂ concentrations and gas-phase losses of NO₃, which makes this type of analysis unviable. Similar observations of apparently negative gas-phase reactivity indicating breakdown of the steady-state method have previously been made (Morgan et al., 2015; Brown et al., 2016a). In addition to co-variance between NO₂ and other trace-gases that are reactive to NO₃, negative intercepts can also result from analysis of time periods in which steady state was not acquired. During the PARADE campaign there were only three clear examples of the expected relationship between the NO₃ lifetime and NO₂ mixing ratios as defined by Eqs. (7) or (8). This indicates that, over periods of a few hours, the changes in the NO₃ lifetime observed cannot be attributed solely to different rates of heterogeneous processing but that other air mass characteristics (e.g. influencing the gas-phase losses of NO₃) are also variable, which may be expected in a region that is impacted by fresh emissions of reactive gases. We also note that the average aerosol surface area during the PARADE campaign was about $70 \mu\text{m}^2 \text{ cm}^{-3}$, which is low compared to the ones reported, e.g. by Aldener et al. (2006), Brown et al. (2006) and Brown et al. (2009), which range from 200 to $600 \mu\text{m}^2 \text{ cm}^{-3}$ and where plots of inverse NO₃ lifetime against $0.25\bar{c}A K_{\text{eq}}[\text{NO}_2]$ resulted in straight lines and returned reasonable values of γ . We conclude that the steady-state approach to derive γ is best suited to air masses with high aerosol loading but remote from fresh emissions and only worked on a few occasions during the PARADE campaign when NO₃ was sampled from the residual layer. The overall uncertainty associated with the determination of γ via the steady-state method is derived from uncertainty in the mixing ratios of O₃ (5%) and NO₃ (25%), the aerosol surface area ($\sim 70\%$), the rate constant for reaction between O₃ and NO₂ (15% at 298 K; Atkinson et al., 2004) and the equilibrium constant, K_{eq} (20% at 298 K, Burkholder et al., 2016) and when propagated in quadrature is equal to $\pm 75\%$. The three values of γ obtained by the steady-state method (with total uncertainty) are also plotted in Fig. 8.

4.3 Method 3: iterative box model of N₂O₅ formation and loss

A further method for deriving N₂O₅ uptake coefficients is to use a box model of NO₃ / N₂O₅ formation and loss (both

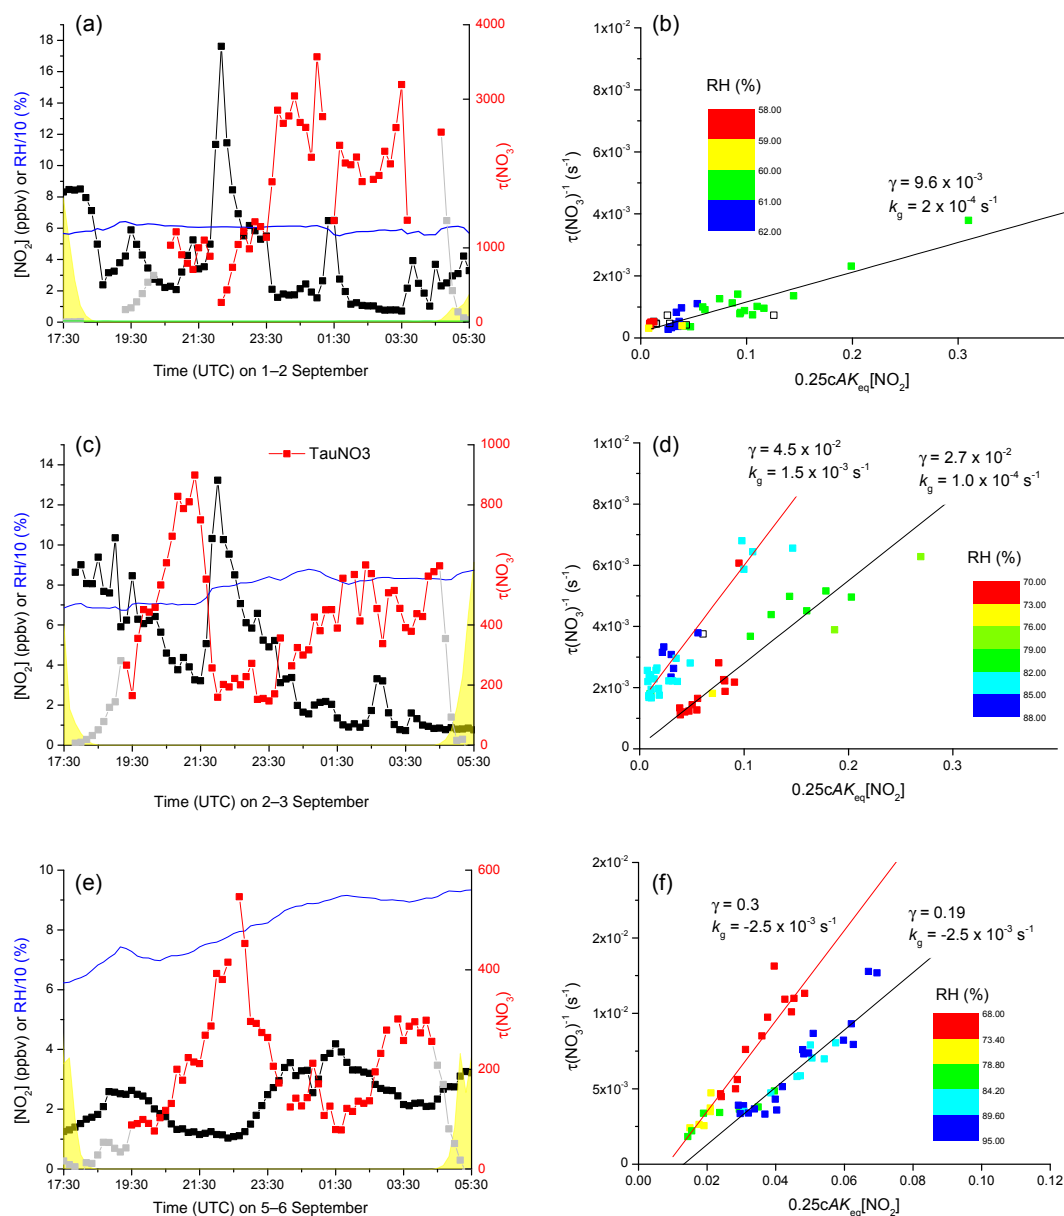

Figure 9. Derivation of γ via analysis of NO_3 steady-state lifetime variation with NO_2 . The grey $\tau(\text{NO}_3)$ data points were not considered in the analysis as NO_3 will not always be in steady state in the first hours after sunset or during sunrise.

gas-phase and heterogeneous) with γ treated as a variable to match observed N_2O_5 concentrations. Such an analysis was conducted by Wagner et al. (2013), who used an iterative box model of N_2O_5 chemistry to estimate the uptake coefficient that would be needed to account for the N_2O_5 concentration measured at the observation point at time t after sunset. The calculations were constrained by on-site measurements of N_2O_5 precursor gases (NO_2 and O_3) which were used to estimate the original NO_2 and O_3 concentrations (i.e. at sunset) for the same air mass, and measurements of the aerosol surface area. As the concentration of N_2O_5 at any time after sunset depends not only on its heterogeneous loss processes

but also on gas-phase losses of NO_3 , the total NO_3 reactivity must also be known. As Wagner et al. (2013) point out, this can be a poorly constrained parameter, as potentially not all reacting VOCs are measured and the reactions of NO_3 with other trace gases including NO and RO_2 during transport to the measurement site cannot be accurately assessed. This method is, therefore, expected to be least accurate when gas-phase losses of NO_3 are a substantial fraction of the overall loss rate of NO_3 and N_2O_5 . During much of the PARADE campaign and for previous measurements at this site (Crowley et al., 2010), NO_3 lifetimes were dominated by gas-phase losses and, on the few occasions when NO_3 was long-lived,

this was due to sampling from a residual layer that was decoupled from boundary layer emissions. As we have recently shown (Sobanski et al., 2016) when sampling from the residual layer, measured VOC mixing ratios at the site are incompatible with the high NO_3 and N_2O_5 levels observed and a box model approach that requires a constraint on gas-phase losses of NO_3 cannot provide reliable results. For this reason, we have not attempted to analyse our data in a similar fashion to Wagner et al. (Wagner et al., 2013).

4.4 Factors affecting the ClNO_2 formation efficiency, f

From the PARADE dataset, we derived values of f that ranged from 0.029 ± 0.027 to 1.38 ± 0.60 , with a mean value of 0.49. To put these numbers into context, we rearrange Eq. (2) and use a k_2/k_4 ratio of 2.2×10^{-3} to calculate which particulate chloride concentrations would be required to explain the values of f observed (Eq. 7).

$$[\text{Cl}^-] = 2.2 \times 10^{-3} [\text{H}_2\text{O}] / (f^{-1} - 1) \quad (9)$$

Assuming that the fate of H_2NO_3^+ is reaction with Cl^- and H_2O and taking a water concentration of ~ 40 M, we obtain $f \sim 0.035$ (at the lower limit of values obtained) when N_2O_5 is taken up to particles with $[\text{Cl}^-] = 3.4 \times 10^{-3}$ M. For $[\text{Cl}^-] = 0.85$ M, $f \sim 0.9$. Chloride concentrations exceeding 1 M may be found in sea-salt particles, which have $[\text{Cl}^-]$ close to 5 M when freshly generated (Sander and Crutzen, 1996). While the sodium content of the particles is conserved during transport, there are mechanisms by which chloride may be lost to the gas-phase including acid displacement of HCl following uptake of HNO_3 or H_2SO_4 as well as reactive losses via uptake of N_2O_5 and other inorganic trace gases and radicals (Keene et al., 1990, 1999; von Glasow et al., 2001). The presence of chloride in non-marine aerosol is related to the uptake of HCl to particles and formation of ammonium chloride, where the HCl may be either of anthropogenic or marine origin. As discussed by Phillips et al. (2012), there is indirect evidence for the presence of aged, sea-salt aerosol at the Kleiner Feldberg site during the PARADE campaign, which is largely based on the dependence of ClNO_2 on air mass origin as derived from back-trajectories and wind-direction measurements. During a campaign (INUIT, Phillips et al., 2013a) at the same site and time of year in 2012, we measured the inorganic particle composition via ion chromatography and showed that the site is regularly impacted by marine aerosol during periods of strong north-westerly winds. During INUIT, high concentrations of particulate inorganic chloride (up to $\sim 2 \mu\text{g m}^{-3}$) were strongly correlated with sodium (up to $\sim 1.6 \mu\text{g m}^{-3}$) with a chloride/sodium molar mixing ratio that was significantly lower than unity, indicating loss of chloride from sea-salt during transport from the coastal source regions (~ 400 km distance). For the purpose of illustration, 1000 deliquesced particles cm^{-3} with an average diameter of 300 nm and a 0.85 M chloride concentration (as derived from our measurement of f) would result in

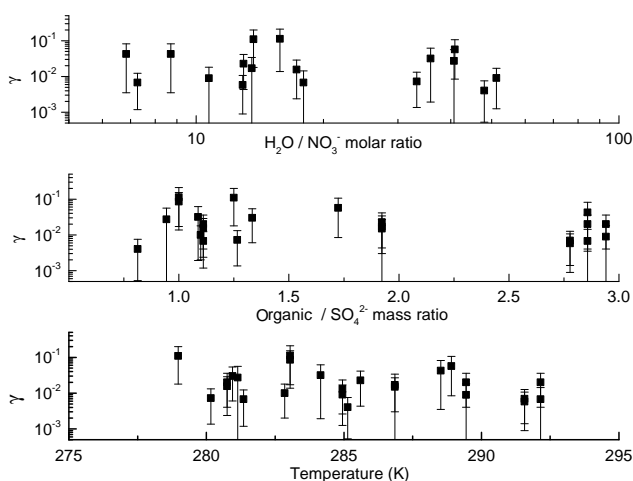

Figure 10. Plot of γ and temperature, molar ratio of particle H_2O to particulate nitrate and the particle organic-to-sulfate mass ratio. Error bars are total uncertainty, calculated as described in the text.

$\sim 0.4 \mu\text{g m}^{-3} [\text{Cl}^-]$ suggesting that the high values of f obtained are compatible with chloride particle concentrations at this site, albeit not measured simultaneously. A high efficiency of ClNO_2 formation ($f > 0.5$) was measured in the period between 29 August and 03 September for which 2-day back-trajectories indicate that the site was influenced by marine air near the UK (Phillips et al., 2012). Over this period, NR PM_{10} Cl^- increases on a number of occasions in concert with nocturnal ClNO_2 production.

The lower values of f derived (e.g. 0.035) are associated with mM $[\text{Cl}^-]$ particle concentrations and are likely the result of N_2O_5 uptake to non-marine particles to which HCl has partitioned during transport.

4.5 Factors affecting the N_2O_5 uptake efficiency, γ

The average value of γ derived from the PARADE dataset from methods 1b, 1c and steady-state analysis is 0.028 with a large standard deviation (0.029) reflecting the high variability in this parameter. No significant dependence on temperature was observed (Fig. 10).

The values of γ derived from the PARADE dataset are compared in Fig. 8 to those predicted from different parameterizations available in the literature, all derived from laboratory studies. The parameterization listed by the IUPAC panel considers, via the resistor model, the dependence of γ on the bulk accommodation coefficient (α_b), the solubility (H) and diffusivity (D_l) of N_2O_5 and the rate coefficient, $k_{\text{H}_2\text{O}}$, for its hydrolysis (Eq. 10).

$$\gamma_{\text{IUPAC}} = \left\{ \frac{1}{\alpha_b} + \frac{\bar{c}}{4HRT(D_l k_{\text{H}_2\text{O}} [\text{H}_2\text{O}])^{0.5}} \right\}^{-1} \quad (10)$$

IUPAC preferred values are listed (for ammonium sulfate) as $\alpha_b = 0.03$, $k_{\text{H}_2\text{O}} = 1.0 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$, $D_l =$

$1 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ and $H = 2 \text{ M atm}^{-1}$. Particle liquid water content $[\text{H}_2\text{O}(l)]$, was calculated with the E-AIM model (<http://www.aim.env.uea.ac.uk/aim/model3/model3a.php>) (Clegg et al., 1998; Wexler and Clegg, 2002) using particulate nitrate, sulfate and ammonium concentrations measured by the AMS and the relative humidity.

The more complex parameterization of Bertram and Thornton (2009) (henceforth referred to as BT) considers the concentrations of particulate nitrate, $[\text{NO}_3^-]$, chloride, $[\text{Cl}^-]$ and water $[\text{H}_2\text{O}]$ (Eq. 11).

$$\gamma_{\text{BT}} = Ak_1 \left(1 - \frac{1}{\left(\frac{k_2[\text{H}_2\text{O}(l)]}{k_{-1}[\text{NO}_3^-]} \right) + 1 + \left(\frac{k_4[\text{Cl}^-]}{k_{-1}[\text{NO}_3^-]} \right)} \right), \quad (11)$$

where $A = 3.2 \times 10^{-8} \text{ s}$, $k_1 = 1.15 \times 10^6 - 1.15 \times 10^6 \exp(-0.13[\text{H}_2\text{O}(l)]) \text{ s}^{-1}$, $k_2/k_{-1} = 0.06$ and $k_4/k_{-1} = 29$ as empirically derived and listed in Bertram and Thornton (2009). We refer to the calculated values of γ as γ_{IUPAC} and γ_{BT} respectively.

Other parameterizations have been developed which also deal with the effects of particle organics, e.g. as a particle coating (Anttila et al., 2006), and have been reviewed by Chang et al. (2011). We examine the effects of assuming that a hydrophobic coating covers the particles below.

For the BT parameterization, particulate nitrate, sulfate and ammonium concentrations as measured by the AMS and the relative humidity were then used as input parameters to calculate the particle liquid water content $[\text{H}_2\text{O}(l)]$ using the E-AIM model (<http://www.aim.env.uea.ac.uk/aim/model3/model3a.php>) (Clegg et al., 1998; Wexler and Clegg, 2002). The particulate chloride content was calculated using values of f derived as described above and in Eq. (2). In those cases where f exceeded unity, it was set to 1.0 for calculation of particulate chloride content (Eq. 7) to avoid generation of negative concentrations. For the γ values obtained using the steady-state method, the chloride content is unknown and was set to zero. Given insufficient information on the identity of the condensed organics or particle hygroscopicity, the influence of particle organic content on the particle water was not considered.

γ_{BT} (red stars) and γ_{IUPAC} (blue stars) were computed for each observational data point in Fig. 8. On average, the predictions and the measurements are in reasonable agreement. The variability in the γ_{BT} predicted values (for a given RH) stems from different particulate chloride content. As an example of the sensitivity to chloride, the low value predicted for 70 % RH in Fig. 8 was obtained for a calculation of uptake to particles which had a high nitrate content and, as the chloride content was not known for this particular period (γ was derived using the steady-state method), it was set to zero. Adding $\sim 0.02 \text{ M}$ chloride to the calculation (equivalent to $f \sim 0.2$) would increase the calculated γ by $\sim 40 \%$ (from 0.007 to 0.01). The BT-predicted γ , averaged over the

same time periods as the measured values, is (0.028 ± 0.008) . This is entirely consistent with the campaign-averaged value derived from methods 1b and 1c of (0.025 ± 0.027) , as described above. However, the BT- parameterization lies at the upper range of the measurements for relative humidities between 65 and 75 % and at the lower end for the highest relative humidities encountered. This may indicate a positive dependence of measured γ on RH which is not predicted by the parameterizations. As the particles during PARADE have significant organic content (see Fig. 2) this may reflect the fact that the organic suppression of γ is reduced at high relative humidity as reported by Gaston et al. (2014). We note, however, that the values of γ measured at large RH are larger than most measurements on pure laboratory samples, which may indicate a measurement bias under some conditions.

As already stated, the BT parameterization accounts for a reduction in γ due to particulate nitrate but does not take the effect of particle organic content into account. γ values derived from observation of N₂O₅ uptake to ambient particles in Seattle (Bertram et al., 2009b) have revealed that the uptake coefficient can be dependent on the sulfur-to-organic ratio, with reduced uptake at low ratios. In Fig. 10, we plot the measured uptake coefficients against the molar H₂O / nitrate ratio of the particles and the organic-to-sulfate ratio. Despite significant variation in both nitrate content (~ 0.2 to $7 \mu\text{g m}^{-3}$) and the organic-to-sulfate ratio (0.3–1.2), no trend is seen. The PARADE γ s are nonetheless consistent with the Seattle observations reported by Bertram et al. (2009b) in which γ was close to 3×10^{-2} for organic/sulfate ratios up to 3. The large organic/sulfate ratios up to ~ 13 observed by Bertram et al. were not encountered during the PARADE campaign. As discussed by Gaston et al. (2014) and Gržinic et al. (2015), the effect of organic content in a particle will depend on the amount and oxidation state of the organics, with both solubility and viscosity impacting on the response of γ to changes in relative humidity.

The lack of a measurable dependence on particulate nitrate content may be contrasted with the interpretation of Morgan et al. (2015), who report that the uptake coefficients they derived in their steady-state analysis of airborne data ($0.03 > \gamma > 0.007$) reveal a dependence on the H₂O / nitrate ratio, as would be expected from Eq. (8), with the lower values of γ associated with high nitrate content. The larger scatter in uptake coefficients in the present study would most likely disguise this effect. In addition, the formation of ClNO₂ is an unambiguous confirmation of the presence of chloride in the particles, which will efficiently counter the reduction in γ caused by nitrate. We also note that the effect of particulate nitrate content is difficult to assess for the PARADE campaign. As we have already shown for this site (Phillips et al., 2013a), a major fraction of the particulate nitrate is in any case the result of N₂O₅ uptake, so that efficient uptake (i.e. high values of γ) may be accompanied by large nitrate concentrations, essentially implying a time dependence to γ as the uptake proceeds (and particulate nitrate

increases) or, in other words, an apparent dependence of γ on N₂O₅ levels. While such effects are reported in laboratory experiments they will be very difficult to observe in ambient datasets and we see no dependence of γ on the N₂O₅ levels.

We have also examined the possibility that the formation of ClNO₂ occurs only in coarse particles, i.e. with >0.5 μm diameter as measured by the APS. In this case, assuming the coarse particles to be sea-salt we fixed γ at 0.02. (Ammann et al., 2013). Similarly to the conclusions of Mielke et al. (2013), we find that, even when the ClNO₂ efficiency is optimized by setting f to 1, only a fraction ($\sim 20\%$) of the ClNO₂ observed can be accounted for. This indicates that chloride is distributed across the particle size spectrum and, after 2–3 days of transport across polluted NW Europe, is also in the form of gas-phase HCl in equilibrium with ammonium chloride as well as in coarse particles like NaCl.

The presence of an organic coating can reduce the uptake coefficient of N₂O₅ to an aqueous particle and a parameterization of γ based on laboratory studies has been developed to account for this (Mentel et al., 1999; Anttila et al., 2006; Riemer et al., 2009). In this case, the uptake coefficient is given by

$$\gamma_{\text{coating}} = \frac{4R T H_{\text{org}} D_{\text{org}} R_{\text{aq}}}{\bar{c} L R_{\text{part}}}, \quad (12)$$

where H_{org} and D_{org} are the solubility and diffusivity respectively of N₂O₅ in the organic coating (of thickness L). R_{aq} and R_{part} are the radii of the aqueous core and the particle. In order to calculate the thickness of the coating, we assume that the entire organic content of the particle is hydrophobic, has a relative density of 1.27 and forms a coating on an aqueous, inorganic core (of density 1.28 as returned from the E-AIM calculation). We set $H_{\text{org}} D_{\text{org}}$ to $0.03 \times H_{\text{aq}} D_{\text{aq}}$ as derived by Anttila et al. (2006) in their laboratory studies with $H_{\text{aq}} = 5 \text{ mol L}^{-1} \text{ atm}^{-1}$ and $D_{\text{aq}} = 10^{-9} \text{ m}^2 \text{ s}^{-1}$. The net uptake to a particle with an aqueous core (containing nitrate and chloride) and an organic coating is then given by:

$$\frac{1}{\gamma_{\text{net}}} = \frac{1}{\gamma_{\text{BT}}} + \frac{1}{\gamma_{\text{coating}}} \quad (13)$$

As shown in Fig. 8, the effect of the organic coating can be substantial and values of γ_{net} obtained are significantly lower than those calculated from the BT parameterization and the observations. This is not totally surprising, as a significant fraction of the organic content of an aged particle is likely to be soluble in water, which means that the assumed thickness of the organic coating is an upper limit and the effect of organic in suppressing γ is overestimated (Gaston et al., 2014). Conversely, as discussed by Gržinic et al. (2015), the increase in viscosity driven by the presence of oxidized organics may lead to a reduction in diffusive transport into the particle.

The scatter in our data and the missing information regarding the chemical nature of the organics in the particle (to get

realistic values of H_{org} and D_{org}) do not allow us to further evaluate the role of organics in suppressing γ .

4.6 Comparison of γ and f with literature values derived from ambient datasets

Previous determinations of γ from ambient datasets are summarized along with the results of this work in Table 1. The reported values of γ vary over more than 2 orders of magnitude, between 0.0005 to ~ 0.1 . The directly measured loss rates of N₂O₅ to ambient aerosol (Bertram et al., 2009b; Riedel et al., 2012b) convert to variable values of γ (~ 0.005 – 0.035) in Seattle (RH $\sim 74 \pm 13\%$), which are comparable to those reported in this work. The largest values of γ were obtained at low organic-to-sulfate ratios, whereas their largest values at a coastal location impacted by chloride containing aerosol were obtained when the molar H₂O / NO₃⁻ ratio was high. In drier conditions in Boulder (RH < 30%) γ was much lower (< 0.005) and independent of the organic-to-sulfate ratio.

Apart from the present study, the steady state method using NO₃ lifetimes has been successfully used for analysis of aircraft data (Brown et al., 2006, 2009; Morgan et al., 2015) and ship data (Aldener et al., 2006) as well as in ground-based studies in which residual layer air was sampled (Brown et al., 2016a). In their airborne studies over the NE US, Brown et al. (2006) report regional differences in γ which they assign to changes in the sulfate content or sulfate-to-organic ratio of the particles. In a further airborne study over Texas, Brown et al. (2009) analysed several residual layer plumes to derive ~ 30 values of γ between 5×10^{-4} and 0.006 during three flights. They found no dependence of γ on RH or aerosol composition, which was typically ammonium sulfate with an organic fraction of > 50%. In contrast, airborne measurements over Europe (Morgan et al., 2015) suggest that γ is larger and dependent on the particulate nitrate content. Measurements of NO₃ and N₂O₅ on a polluted mountain site in Hong Kong (Brown et al., 2016b), enabled 10 derivations of γ which varied between 0.004 and 0.029. Measurements of ClNO₂ at the same location indicate that N₂O₅ uptake was, at least partially, to chloride-containing particles. Values of (0.03 \pm 0.02) for γ obtained over the ocean (Aldener et al., 2006) are, on average, at the higher range of ambient measurements, potentially reflecting the role of particulate chloride.

In their analysis of N₂O₅ and ClNO₂ datasets obtained during CalNex-LA at a coastal location, Mielke et al. (2013) did not derive separate values of f and γ but report a composite term, γf . For submicron particles, values of γf vary ~ 2 orders of magnitude during a single night with campaign minimum values close to 10^{-4} and maximum values of 0.05. In comparison, γf values from the present study vary between ~ 0.001 and 0.09. Mielke et al. (2013) report a campaign average value of $\gamma f = 0.0084$, which is similar to the average value of $\gamma f = 0.014$ obtained in the present study.

Table 1. Values of γ derived from ambient datasets.

Platform (location/height)	γ (method)	Notes	Reference
Ship (East Coast US, 11 m)	0.03 ± 0.02 (ss)	Polluted marine	Aldener et al. (2006)
Aircraft (NE-US < 1.5 km)	< 0.0016–0.017 (ss)	Continental/coastal residual layer. γ dependence on organic/sulfate content.	Brown et al. (2006)
Aircraft (Texas, US < 1 km)	0.0005–0.006 (ss)	Continental/coastal residual layer. γ variable but independent of RH or aerosol composition	Brown et al. (2009)
Ground (US, Seattle/Boulder 5–10 m)	< 0.01–0.04 (AFR)	Urban/suburban environment. γ dependence on organic/sulfate ratio and RH.	Bertram et al. (2009b)
Ground (US, La Jolla, 15 m)	< 0.001–0.029 (AFR)	Polluted coastal environment. γ dependence on nitrate content	Riedel et al. (2012b)
Ground (US, Boulder 10–300 m)	0.002–0.1 (box model)	Continental, pollution impacted boundary layer/residual layer. γ dependence on nitrate content	Wagner et al. (2013)
Aircraft (NW Europe 500–1000 m)	0.01–0.03 (ss)	Continental, pollution impacted residual layer/free troposphere. γ dependence on nitrate content	Morgan et al. (2015)
Ground US, Pasadena (10 m)	$\gamma f = 0.008$ (av)	Coastal (CalNex-LA). γf was suppressed by particle organic content and enhanced by particulate chloride content.	Mielke et al. (2013)
Ground China, Hong Kong, (957 m)	0.004–0.029 (ss)	Coastal, pollution impacted mountain site.	Brown et al. (2016a)
Ground (SW Germany, 825 m)	0.004–0.11 (1b, 1c, ss)	Semi-rural mountain site with anthropogenic influence, mixed boundary layer / residual layer	This work

Notes: ss is steady-state analysis. AFR is aerosol flow reactor. Av is averaged over a campaign.

Similar values may indeed be expected despite the different locations (semi-rural mountain site in PARADE and polluted coastal in CalNex-LA) as most of the γ values reported in the present work were derived using ClNO₂ observations, i.e. for particles with chloride content as would certainly be expected at the coastal location.

Wagner et al. (2013) used a box model and observations of N₂O₅ to derive highly scattered values of γ with two peaks in the frequency distribution at 0.015 and 0.04, lower values of γ being associated with higher particulate nitrate content. As discussed above, this method for deriving γ requires knowledge of the NO₃ lifetime with respect to gas-phase losses, and the authors suggest that uncertainty in this parameter may result in values of γ that are too high. The source of the very high scatter in γ derived by this method is unlikely to be related to aerosol composition, but probably results from the large variability of N₂O₅ (and NO₃) frequently observed in ground-based measurements, which is the result of sampling advected air masses with strong vertical gradients in NO₃ in a poorly mixed boundary layer at night.

In summary, the derivation of γ from ambient datasets reveals great variability in the values obtained, with occasional evidence for a suppressing role of particulate organics and nitrate (though not in the present study), which is consistent with laboratory observations.

The large spread in f derived in the present study is consistent with previous analyses of field measurements in

which values between < 0.01 and > 0.9 have been reported (Riedel et al., 2012b; Wagner et al., 2013; Young et al., 2013). The large spread in f is to be expected as this parameter is controlled largely by particulate chloride content, although, as mentioned already, some dissolved organic species may compete with Cl[−] for reaction with NO₂⁺ and thus reduce the ClNO₂ yield for a given chloride content. We thus expect f to be largest in polluted coastal regions (unless there is a large organic content that can react with H₂NO₃⁺) and lowest (or zero) in continental regions with no marine influence or anthropogenic chlorine emissions.

5 Conclusions

We present estimates of γ using ambient measurements of gas and particle composition at the Kleiner Feldberg observatory, near Frankfurt, SW Germany, during the PARADE observational experiment in the summer of 2011. Values of γ were derived using different methods and reveal high variability with 0.004 < γ < 0.11 and an average value of 0.028 ± 0.027. The results are compared with different parameterizations based on laboratory data and are in reasonable agreement when we neglect the potential effect of an organic coating on the particle but account for inorganic composition and relative humidity (Bertram and Thornton, 2009). The assumption that the organic fraction of the particle is in the

form of a hydrophobic coating (Anttila et al., 2006) results in predicted γ values that are inconsistent with our dataset and is clearly inappropriate for the aerosol encountered during the PARADE campaign. There is an urgent need for further laboratory work on synthetic aerosols and more field measurements that investigate the uptake of N₂O₅ in different “real-world” environments, especially chemically complex ones as found in the continental boundary layer.

6 Data availability

Datasets from the PARADE campaign are archived at the Max-Planck-Institute and may be obtained on request through John Crowley to the owner.

Acknowledgements. We would like to thank the staff and department of the Johann Wolfgang Goethe-University, Frankfurt am Main for logistical support and the use of the Taunus Observatory. We acknowledge the help and support of all PARADE participants and our colleagues in the Department of Atmospheric Chemistry, MPIC.
