Abstract

Using observations from aircraft, surface stations and satellite, we comprehensively evaluate multi-model simulations of carbon monoxide (CO) and ozone (O₃) in the Arctic and over lower latitude emission regions, as part of the POLARCAT Model Inter-comparison Project (POLMIP). Evaluation of eleven atmospheric models with chemistry shows that they generally underestimate CO throughout the Arctic troposphere, with the largest biases found during winter and spring. Negative CO biases are also found throughout the Northern Hemisphere, with multi-model mean gross errors (9–12%) suggesting models perform similarly over Asia, North America and Europe. A multi-model annual mean tropospheric OH ($10.8 \pm 0.6 \times 10^5 \text{ molec cm}^{-3}$) is found to be slightly higher than previous estimates of OH constrained by methyl chloroform, suggesting negative CO biases in models may be improved through better constraints on OH. Models that have lower Arctic OH do not always show a substantial improvement in their negative CO biases, suggesting that Arctic OH is not the dominant factor controlling the Arctic CO burden in these models. In addition to these general biases, models do not capture the magnitude of CO enhancements observed in the Arctic free troposphere in summer, suggesting model errors in the simulation of plumes that are transported from anthropogenic and biomass burning sources at lower latitudes. O₃ in the Arctic is also generally underestimated, particularly at the surface and in the upper troposphere. Summer O₃ comparisons over lower latitudes show several models overestimate upper tropospheric concentrations.

Simulated CO, O₃ and OH all demonstrate a substantial degree of inter-model variability. Idealised CO-like tracers are used to quantitatively compare the impact of inter-model differences in transport and OH on CO in the Arctic troposphere. The tracers show that model differences in transport from Europe in winter and from Asia throughout the year are important sources of model variability at the Barrow. Unlike transport, inter-model variability in OH similarly affects all regional tracers at Barrow. Comparisons of fixed lifetime and OH-loss idealised CO-like tracers throughout the Arctic

5 troposphere show that OH differences are a much larger source of inter-model variability than transport differences. The concentration of OH in the models is found to be correlated with inter-model differences in H₂O, suggesting it to be an important driver of differences in simulated concentrations of CO and OH at high latitudes in these
10 simulations. Despite inter-model differences in transport and OH, the relative contributions from the different source regions (North America, Europe and Asia) and different source types (anthropogenic and biomass burning) are comparable across the models. Fire emissions from the boreal regions in 2008 contribute 33, 43 and 19% to the total Arctic CO-like tracer in spring, summer and autumn, respectively, highlighting the importance of boreal fire emissions in controlling pollutant burdens in the Arctic.

1 Introduction

15 During the 20th century, regions poleward of 60° N have warmed at a rate 50% greater than the Northern Hemisphere (NH) average (0.09 °C decade⁻¹ compared to 0.06 °C decade⁻¹) (ACIA, 2005). This is due to feedback mechanisms, such as the snow and sea-ice-albedo feedback, where melting ice leads to increased absorption of solar radiation, which further enhances warming in the Arctic (Serreze and Francis, 2006). Studies have shown that Arctic temperatures respond to both local and non-
20 local radiative forcing, meaning that reducing emissions of greenhouse gases and their precursors throughout the Northern Hemisphere will be beneficial in slowing Arctic warming (Shindell, 2007). Shindell and Faluvegi (2009) estimated that anthropogenic emissions of black carbon (BC) and secondary production of tropospheric ozone (O₃) from anthropogenic precursor emissions have contributed 0.5–1.4 and 0.2–0.4 °C to Arctic warming since 1890, respectively. The short lifetimes of these species compared to carbon dioxide (CO₂), mean that emission reduction measures that target
25 these species in conjunction with CO₂ could offer a more immediate abatement of climate warming than measures targeting solely CO₂ (Quinn et al., 2008). Consequently,

Interactive Discussion

5 a loss of HO_x from the atmosphere, needs to be included in models in order to increase concentrations of winter/spring CO. The generally poor skill and large variability of global models in simulating Arctic burdens of these species has implications for our confidence in a model's ability to accurately simulate climate responses to changes in mid-latitude emissions. Therefore, there is a need to better understand the chemical and physical processes that lead to these model differences and biases.

10 An improvement in this understanding is largely limited by a paucity of observations of chemical constituents throughout the Arctic troposphere, particularly away from the surface, where enhancements from more southerly sources in North America and Asia are more likely to be found (Klonecki et al., 2003). The POLARCAT (POLAr study using Aircraft, Remote Sensing, surface measurements and models of Climate, chemistry, Aerosols, and Transport) campaign intensively sampled the Arctic and sub-Arctic during spring and summer 2008, as part of the International Polar Year (Law et al., 2014). The POLARCAT Model Intercomparison Project (POLMIP) aims to exploit this observational dataset to evaluate models in the Arctic and sub-Arctic (Emmons et al., 2014). In this study, we use POLMIP simulations of CO, O₃ and OH in conjunction with POLARCAT aircraft observations, surface measurements and satellite observations, within the Arctic and near source regions to evaluate model performance (Sect. 4). The availability of the aircraft observations in the Arctic allows a more extensive multi-model evaluation of models within a variety of air-mass types in the Arctic than previously undertaken. Idealised tracers are used to provide a useful summary of the relative importance of anthropogenic and biomass burning sources from several models throughout the year 2008 and to investigate inter-model differences in these source contributions (Sect. 5). The aim of this paper is to provide a better understanding of inter-model differences in simulated Arctic trace gases.

Interactive Discussion

DC8 aircraft was based in Fairbanks, Alaska from 1st–21 April 2008 during ARCTAS-A and then in Cold Lake, Canada from 29 June–10 July 2008 during ARCTAS-B (Jacob et al., 2010). OH was measured by laser induced fluorescence aboard this flight, which has relatively high measurement uncertainties ($\pm 40\%$) (Brune et al., 1999). The POLARCAT-GRACE and POLARCAT-France projects had two aircraft jointly based in Kangerlussuaq, Greenland in summer. The POLARCAT-France ATR-42 measured CO using an infrared absorption analyser (Nédélec et al., 2003) and O₃ using an UV absorption instrument (Ancellet et al., 2009). The POLARCAT-GRACE Falcon also measured CO but used a vacuum UV fluorescence instrument (Gerbig et al., 1999) and O₃ was measured using a UV absorption analyser (Roiger et al., 2011). Even though based at the same location, the Falcon had a larger range than the ATR-42 and was able to cover larger regions and higher altitudes. The POLARCAT flight tracks are shown in Fig. 1.

4 Model evaluation

In this section, POLMIP model simulations are evaluated against Arctic surface CO and O₃ data and MOPITT CO retrievals throughout the year 2008. Aircraft measurements of CO, O₃ and OH from the POLARCAT and MOZAIC projects are then used to evaluate the vertical structure of the troposphere during intensive periods of sampling in April and June–July 2008. Model performance against the observations is summarised in Fig. 10 using the normalised mean gross error (NMGE), which gives the mean model bias (regardless of sign) over the vertical column or over the year as a percentage of the observed concentrations.

4.1 Seasonality of carbon monoxide and ozone

4.1.1 Arctic surface comparisons of carbon monoxide and ozone

Figure 2 shows the time series of monthly mean 2008 simulated and observed concentrations of CO at Barrow and Zeppelin and O₃ at Barrow and Summit (stations located north of the Arctic Circle). These models use the same emissions data, removing one key inter-model difference in Arctic surface CO and O₃ comparisons identified in Shindell et al. (2008). The overall model performance at several Arctic stations (shown in Fig. 1) is summarised as Taylor diagrams in Fig. 3. Perfect agreement between a model and observations would result in a normalised standard deviation (NSD) of 1, a correlation (r) of 1 and a centered root-mean-square difference (RMSD) of 0 (indicated by “Observed” on the Taylor diagram).

The models capture the seasonality in CO, with correlations greater than 0.8 at all surface stations. The models show a large range in their ability to capture the amplitude of the observed seasonal cycle ($0.3 \leq \text{NSD} \leq 1.2$). RMSDs are mostly clustered between values of 1 and 2. As this error statistic is weighted by monthly deviations from the annual mean, the models with a higher RMSD are the models which do not capture the amplitude of the seasonal cycle well. Figure 4 shows box and whisker plots of simulated seasonal mean surface CO bias at Barrow and Zeppelin. The median biases tend to lie below the zero line, showing that models generally underestimate CO throughout the year. However, the median biases are near zero in autumn, with some models overestimating CO in summer and autumn. The largest negative median biases occur during winter at Barrow and during spring at Zeppelin, with the smallest median biases occurring during autumn at both stations. This shows that state-of-the-art models still consistently underestimate winter/spring Arctic surface CO as shown in previous studies (e.g. Shindell et al., 2006, 2008).

Two models, GEOS-Chem and LMDZ-INCA, stand out from the other models in winter/spring, showing much better agreement with the observations due to higher simulated CO concentrations compared to other models. The version of the GEOS-Chem

Median biases of O₃ at these two stations (see Fig. 4) show that the models generally underestimate O₃ throughout the year at the surface, with the exception of spring at Barrow, in agreement with Shindell et al. (2008) The POLMIP models have RMSE of 5–10 ppbv averaged over Summit and Barrow, which is slightly lower than the RMSE of 7–12 ppbv from Shindell et al. (2008). At Barrow, the largest positive median bias occurs during spring (due to ODE) and the largest negative median bias occurs during winter. In contrast, the largest negative bias at Summit occurs during spring, closely followed by summer. It should also be noted that, whilst simulated O₃ seasonality at Summit shows much better agreement with the observations, the absolute median model bias is larger compared to that at Barrow. The high altitude of Summit (3238 m) makes this station highly sensitive to stratospheric ozone enriched air (Helmig et al., 2007; Hirdman et al., 2010), explaining the higher O₃ concentrations. Therefore the higher absolute bias at this station may indicate an underestimate in the stratospheric source of O₃.

4.1.2 MOPITT carbon monoxide comparisons

Figure 5 shows the monthly average MOPITT total CO column for April and July 2008 along with the difference between the multi-model mean and MOPITT total column. The multi-model mean was calculated from ten POLMIP model total columns with the averaging kernels applied. Missing data and retrievals where the degrees of freedom signal (DOFS) was less than 1 have been removed from the model and satellite columns.

The highest concentrations in April are observed over eastern Asia near China. This high CO is a result of Asian anthropogenic emissions combined with unusually early and large fires in southern Siberia during April 2008 (Warneke et al., 2010; Brock et al., 2011; Law et al., 2014). MOPITT also exhibits high CO over parts of Europe and North America due to fossil fuel emissions and over western Russia due to agricultural burning (Warneke et al., 2009). It is also possible to see the large-scale continental outflow over the Pacific and Atlantic. The CO concentrations seen by MOPITT are lower in July due to a shorter atmospheric lifetime, however, regions of high CO can still be seen

Interactive Discussion

in the Arctic and over the source regions ($r = 0.94$ – 0.99). At 300 hPa, a lower range in correlations ($r = 0.47$ – 0.98) indicates that the models are less able to capture the seasonal cycle at this altitude. As seen at the Arctic surface, most models underestimate CO at both levels throughout the year. The models which have the lowest/highest concentrations of CO throughout the year in the Arctic also have the lowest/highest concentrations near the source regions suggesting the individual model biases are consistent throughout the NH. The monthly model biases show a seasonal cycle (see bottom panel, Fig. 6), which is present across the different regions and models. At 700 hPa the largest regional biases tend to occur in winter and spring, as found at the Arctic surface stations, and the smallest biases occur in summer. However, at 300 hPa the bias shows the opposite behaviour, where the largest bias in all regions occurs in summer. This suggests that the surface winter/spring bias may be shifted to higher altitudes during summer when vertical mixing of pollutants by convection is important (e.g. Hov and Flatøy, 1997; Donnell et al., 2001; Jaegle, 2007).

Over North America the multi-model normalised mean gross error (NMGE, shown in Fig. 10) is smaller at 700 hPa relative to 300 hPa. Over Europe the NMGE is lower at 300 hPa relative to 700 hPa. The frequency of passing fronts, which export pollutants from the boundary layer to the free troposphere, are more frequent over North America compared to Europe (Stohl, 2001), which results in more rapid vertical transport of pollutants over North America (Wild and Akimoto, 2001). This may be shifting the negative model bias to a higher altitude to a larger extent than over Europe. However, over Asia, which also experiences very rapid vertical transport (Stohl, 2001), the NMGE is similar at 700 and 300 hPa. As can be seen in Fig. 6, there is no information available in the Arctic during winter and the mean DOFS over the Arctic region is much lower than in any other region, suggesting that there is limited information in the MOPITT retrieval in this region, making comparisons between the Arctic and the source regions difficult.

4.2 Vertical structure in the Arctic and Northern Hemisphere

4.2.1 POLARCAT Arctic aircraft comparisons

Aircraft measurements from the spring and summer 2008 POLARCAT campaign allow a detailed insight into model performance in the Arctic throughout the troposphere over regions of Greenland and the Canadian Arctic. The hourly gas-phase species from each model have been linearly interpolated in time and space to the location of the aircraft. The observed and simulated concentrations are separated into 50 hPa bins to give average vertical profiles over all flights. Aircraft profiles of CO, O₃, OH and water vapour for the DC8 spring and summer campaigns are shown in Fig. 7 and profiles of CO and O₃ for the POLARCAT-France and POLARCAT-GRACE summer campaigns are shown in Fig. 8.

ARCTAS-A spring comparisons

In April 2008, the CO and O₃ DC8 observations show a fairly homogeneous profile, with only small changes in concentrations from the surface up to the middle troposphere. Around 50 % of the CO measured came from anthropogenic sources in Asia, North America and Europe, with Asian emissions dominating (25 %) (Bian et al., 2013), most of which was emitted in China and India (Tilmes et al., 2011). Biomass burning emissions also contributed to the sampled CO, causing small enhancements in the observed profile (Bian et al., 2013; Tilmes et al., 2011) that can be seen at around 500 and 750 hPa in Fig. 7. Biomass burning also contributed a few ppbv to the sampled O₃ at the same levels (Wespes et al., 2012). In the upper troposphere, the influence of stratospheric mixing is at its greatest (Wespes et al., 2012), which can be seen by a large increase in O₃ and a concurrent decrease in CO.

The models capture the vertical structure well, yielding correlations of 0.96–0.99 for CO and 0.88–1.00 for O₃, however, only very small CO enhancements are seen in the simulated profiles at the altitude of the boreal fire plumes. This may be due to simulated

Interactive Discussion

concentrations at 300 hPa. This may be related to the different chemical mechanisms in the models, which result in different O₃ production and loss efficiencies (Arnold et al., 2014). Summer OH correlations of 0.25–0.71 are lower than those calculated for the spring profile. In summer more rapid production and loss of OH leads to the observations being more sensitive to local changes in cloud cover, water vapour and O₃, making it even more difficult to simulate small spatial variability. Models show a wide spread in concentrations, however, they mostly lie within the 25th and 75th percentile of observed OH concentration. Model H₂O concentrations show good agreement with observations with the exception of a positive bias in the upper troposphere, as seen in spring. Model H₂O percent errors are slightly higher for most models in summer.

POLARCAT-France and POLARCAT-GRACE summer comparisons

As part of the summer POLARCAT campaign, the POLARCAT-France and POLARCAT-GRACE projects had two aircraft, the French ATR-42 and German DLR Falcon, based in Greenland during June–July 2008 to sample aged pollution transported to the Arctic (Law et al., 2014). For this reason, CO profiles sampled by these two aircraft (see Fig. 8) show lower concentrations compared to the DC8 summer measurements. They sampled a mixture of air types including background air, stratospheric air and plumes from anthropogenic and biomass burning sources that had been transported from North America, Asia and Europe (Law et al., 2014; Tilmes et al., 2011). Evidence of these polluted plumes can be seen in the ATR-42 CO profile at around 500 hPa and in the Falcon CO profile at 400 hPa. As seen during the ARCTAS-B campaign, there is a decrease in Falcon observed O₃ in these plumes relative to the surrounding air. Very little or no local emissions are indicated by CO concentrations that are lower than 100 ppbv being measured in the boundary layer.

As observed, modelled CO over Greenland is lower in comparison to concentrations simulated over the Canadian Arctic during the summer ARCTAS-B campaign. Most models underestimate the summer observed CO and show a large spread in simulated concentrations and their ability to capture the vertical structure ($r = 0.19$ – 0.91 for

troposphere suggesting the influence of stratospheric O₃ may be too low in the models. Figure 10 shows that the multi-model O₃ NMGE is lower for comparisons against the ATR-42 data than it is for Falcon data. This is due to the ATR-42 sampling air that was less influenced by stratospheric air due to lower flight levels.

4.2.2 MOZAIC summer aircraft comparisons near source regions

Profiles of CO and O₃ sampled by MOZAIC aircraft during ascent from and descent to airports over North America and Europe between 18 June–14 July 2008 (the duration of the POLARCAT campaign) are shown in Fig. 9. Overall, the models capture the vertical profiles well, with correlations greater than 0.61 for CO and 0.82 for O₃. For CO, models exhibit a negative bias over both source regions between 2–6 km (~ 800–500 hPa), which is in agreement with the MOPITT comparisons at 700 hPa (see Fig. 6). There is no strong evidence of a larger summertime bias occurring at 9 km (~ 300 hPa) compared to 3 km (~ 700 hPa) as suggested by the MOPITT comparisons. The MOZAIC data shown here was collected at a limited number of locations, therefore the horizontal coverage is not as extensive as the MOPITT data and may explain some of the differences seen between these two observational datasets. For O₃, the models generally lie within the 25th and 75th percentile of observed O₃, with some evidence of O₃ being overestimated in the upper troposphere over Europe. Overall, model biases (NMGE) are larger over Europe compared to North America for CO and O₃ (see Fig. 10).

4.3 Overall model performance

Models tend to underestimate Arctic CO at the surface and throughout the free troposphere, most notably in winter/spring. Similar seasonal biases are also found at lower latitudes. MOPITT retrievals show that the smallest multi-model normalised mean gross error (NMGE) occurs over North America (9%) and the largest over Europe (12%) in the lower troposphere, whilst in the upper troposphere the smallest NMGE

Interactive Discussion

monthly mean OH concentrations and the same transport (run as tracers within the TOMCAT CTM). It should be noted that whilst this will quantify the effect of transport and chemistry on inter-model differences in the idealised CO-like tracers, the results will not directly equate to the same inter-model differences in trace gases such as CO and O₃ due to other important factors, such as secondary CO production from other gases, such as CH₄ and NMHC. Firstly, it is useful to discuss model differences in OH and transport that will be studied using the idealised tracers.

5.1 Model differences in OH

Fig. 11 shows the annual zonal mean OH concentrations from each model, which are used to calculate loss rates for the OH-loss tracers. The primary route for OH production is by photolysis of O₃ in the presence of water vapour (Levy, 1971), with secondary production by recycling of HO₂ and H₂O₂, where the concentrations of NO_x and CO are important factors (Logan et al., 1981). The models simulate the highest concentrations of OH in the tropics, where the amount of incoming sunlight is at its greatest and O₃ is readily photolysed. Even though the models agree on this zonal distribution, the magnitude of OH and the location of the annual mean peak in OH vary. Due the importance of OH in controlling the lifetimes of most reactive trace gases in the atmosphere, these inter-model OH differences have important consequences for CO, both as its primary loss route and as a driver of secondary production from hydrocarbon oxidation.

Previous studies have related inter-model and intra-model changes in OH to variables which control its abundance. Voulgarakis et al. (2013) showed that present day global air-mass weighted OH concentrations from the Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP) models were linearly related to model photolysis rates of O₃ to O(¹D) (JO(¹D)) and total volatile organic carbon (VOC) emissions. Murray et al. (2014) found that differences in the $S_N/S_C^{3/2}$ ratio, where S_N and S_C are the total sources of NO_x and of CO and hydrocarbons, respectively, together with

Interactive Discussion

the global tropospheric OH concentration, however, as OH controls the lifetime of CO it is not surprising to see such a correlation and it is unlikely to explain the spread in OH as the models use the same emission inventories.

Prinn et al. (2001) and Bousquet et al. (2005) estimated annual mean tropospheric air-mass weighted OH concentrations of $9.4 \pm 1.3 \times 10^5$ molec cm⁻³ and $9.8 \pm 1.3 \times 10^5$ molec cm⁻³, respectively, from the lifetime of the methyl chloroform. Eight POLMIP models simulate air-mass weighted global mean OH concentrations of 10.1 – 12.0×10^5 molec cm⁻³ (see Table S1 in the Supplement), with a multi-model mean of $10.8 \pm 0.6 \times 10^5$ molec cm⁻³, which is 10 % higher than the estimate of Bousquet et al. (2005). Bousquet et al. (2005) showed that OH was susceptible to inter-annual fluctuations in concentrations of around $8.5 \pm 1\%$. The POLMIP multi-model mean OH concentration lies slightly outside this range of inter-annual variability, suggesting OH in the POLMIP models may be slightly overestimated. For comparison, multi-model mean OH concentrations of $11.7 \pm 1.0 \times 10^5$ molec cm⁻³ (Voulgarakis et al., 2013) and $11.1 \pm 1.7 \times 10^5$ molec cm⁻³ (Shindell et al., 2006) have been found previously, suggesting OH is also slightly overestimated in other models, assuming estimates of OH from methyl chloroform are correct.

5.2 Model differences in tracer transport

Even though differences exist in the model OH, it is reasonable to expect that some of the model spread in CO is explained by differences in transport. Figure 13 shows the seasonal zonal mean difference between the sum of the simulated 25 day fixed loss regional tracer at two levels, 700 and 900 hPa. Negative values show there is more tracer in the upper 700 hPa level, positive values show that there is more tracer in the lower 900 hPa level and near zero values show a vertically well-mixed column (represented by the dashed line).

The largest positive values are found in the northern extra-tropics/lower mid-latitudes with very low CO differences in the Arctic and the tropics. In the Arctic, the models show near-zero differences in the winter and then negative differences in all other seasons. In

Interactive Discussion

the highest concentrations of the 25 day fixed-loss tracer are located in the lowest altitude bin, with a clear decrease in absolute concentrations as altitude increases. This is in line with previous studies, which have shown poleward transport to occur mostly at low levels during winter (Klonecki et al., 2003; Stohl, 2006). As the year progresses, there is a clear shift in the concentrations to the higher altitude bins as transport of emissions at higher altitudes becomes more important in spring, summer and autumn (Klonecki et al., 2003).

Out of the three regional tracers, the European tracer shows the largest seasonal shift in transport efficiency to the Arctic. This is due to a large seasonal cycle in pollution export pathways from Europe (Duncan and Bey, 2004). The North American and Asian tracers show a much more consistent contribution to the Arctic total tracer concentration throughout the year and troposphere. Europe is the most important anthropogenic source region at the surface in winter, with Asian emissions dominating at the highest altitudes, which is consistent with the concept of the “polar dome”. Similar to Asia, the contribution from North America is larger at higher altitudes, although the magnitude is much smaller. This is most likely due to a combination of lower emissions and different export efficiencies (Stohl, 2006). These are in broad agreement with multi-model idealised tracer results from Shindell et al. (2008), despite differences in emissions, tracer lifetimes and the area of the regions used. Results at the surface and in the mid-troposphere also agree with idealised tracer experiments performed by Klonecki et al. (2003), but differ in the upper troposphere where they showed Asian emissions to have the smallest contribution and North American to have a much larger fractional contribution. Increases in Asian emissions (Ohara et al., 2007) and decreases in European and North American emissions since 1990 (Duncan and Logan, 2008), which will be important in terms of the relative contributions, will be accounted for in the Streets v1.2 emissions inventory used for the POLMIP simulations. Klonecki et al. (2003) used the EDGAR v2.0 CO emission estimates for the year 1990, explaining why the Asian influence is lower than North American in their study.

transport differ. This therefore suggests that differences in model emission inventories are the most likely cause of differences in the relative importance of anthropogenic emission regions in Arctic source contribution studies for the same chemical species (as found here for Asian emissions in the Arctic upper troposphere in comparison to Klonecki et al., 2003).

5.4 Inter-model variability in the Arctic

In this section, inter-model variability in CO and O₃ at Arctic surface stations is discussed whilst the possible causes of variability are explored with the use of the idealised tracers to compare the impact of inter-model differences in transport and OH.

5.4.1 Model variability in carbon monoxide and ozone

The interquartile range (IQR) of simulated CO and O₃ at selected Arctic stations are shown in Fig. 4 (Sect. 4.1.1), both as an absolute value (in ppbv) and as a percent (of the seasonal mean observed concentration). The IQR gives a measure of the amount of spread in the POLMIP models.

For CO, the largest model spread occurs during autumn, when the multi-model mean bias is at a minimum. The lowest model spread occurs during spring, when the multi-model mean bias is high. The magnitude of the IQR is relatively similar across the two stations, suggesting the cause of the model spread may equally affect CO throughout the Arctic. The IQR of modelled O₃ shows a large amount of spread during winter and spring and the lowest amount of model spread during summer. Model spread is larger at Barrow, suggesting that the causes of the model spread do not equally impact the different station locations. In addition, the seasonality in model spread differs between O₃ and CO, suggesting the underlying causes of model spread may depend on the trace gas considered.

Interactive Discussion

differences are highly correlated with differences in model water vapour and photolysis rates, therefore improvements to these variables may reduce inter-model differences in Arctic trace species.

It is important to note that the results shown here are for idealised tracers and that the results may not be directly equated to simulations of CO and O₃, where complex chemistry plays a role. For example, if a model has higher OH than other models, then it is likely to have a faster CO loss rate and therefore lower CO concentrations, however, they will also have faster oxidation of methane and other hydrocarbons and therefore more secondary production of CO to offset the higher loss rate of CO. The extent that two opposing factors offset each other will be model dependent on differences in chemistry schemes. Shindell et al. (2008) concluded that oxidation rates, inferred from correlations between Arctic sensitivities and global CO lifetimes, did cause some inter-model differences in Arctic CO, but this was limited to the upper troposphere. The lack of any correlations in the lower troposphere is likely explained by the opposing impacts of OH on CO loss and secondary CO production, however, OH variability will still be particularly important in the when considering the production and loss terms of many reactive species in the Arctic.

6 Conclusions

We have used a range of surface, satellite and aircraft observations to evaluate multi-model simulations of CO and O₃ in the Arctic and sub-Arctic. The models include the same prescribed emissions for anthropogenic and biomass burning sources, removing one source of inter-model variability identified by previous model intercomparisons (Shindell et al., 2008), allowing the impacts of chemistry and transport differences on Arctic CO and O₃ burdens to be isolated.

The models broadly capture the observed seasonality of CO at the Arctic surface and over the mid-latitude lower troposphere. In agreement with previous studies, models generally underestimate CO in the Arctic at the surface, with the largest biases found

anthropogenic emissions used for the POLMIP model simulations result in similar conclusions in terms of the relative importance of different anthropogenic source regions to emissions sensitivities (ppbv(CO) Tg⁻¹ emitted) to those reported by Shindell et al. (2008). Specifically, European emissions are most important at the surface in winter and Asian and North American emissions are most important at higher altitudes. In this study, emissions from fires in the boreal regions were also considered, and we showed that boreal fires can contribute 33, 43 and 19% to the total tracer in the Arctic in spring, summer and autumn, respectively, demonstrating the importance of fires as a source of Arctic pollution.

Table 1. Participating models in inter-comparison. Y in the tracers column indicates that idealised tracers from model have been used for the transport and chemistry analysis in Sect. 5.

Model	Resolution	Meteorology	Chemistry	Tracers	Reference
CAM4-Chem	1.9° × 2.5°, L56	GEOS-5	MOZART-4	Y	Lamarque et al. (2012)
CAM5-Chem	1.9° × 2.5°, L56	GEOS-5	MOZART-4	Y	Lamarque et al. (2012)
C-IFS	T159, L60	ECMWF-Op.	CB05: 55 species, 85 gas-phase reactions Stratosphere: Operational ECMWF O ₃ analysis	Y	Flemming et al. (2012)
GEOS-Chem	2.0° × 2.5°, L47	GEOS-5	~ 100 species HO ₂ gamma for uptake by aerosol set to 1	N	Mao et al. (2010) Parrella et al. (2012)
GMI	2.0° × 2.5°, L72	GEOS-5	based on GEOS-Chem	Y	Strahan et al. (2007) Duncan et al. (2007)
LMDZ-INCA	3.75° × 1.8°, L39	ECMWF-Int	85 tracers, 264 gas-phase reactions Stratosphere: Ozone sonde climatology	Y	Hourdin et al. (2006) Szopa et al. (2013)
SMHI MATCH	0.75° × 0.75°, L35	ECMWF-Int.	63 tracers, 110 gas-phase reactions Stratosphere: Monthly means from EU-MACC project (MOZART-4)	N	Andersson et al. (2007) Robertson et al. (1999)
MOZART-4	1.9° × 2.5°, L56	GEOS-5	103 tracers, 196 gas-phase reactions, Stratosphere: O ₃ constrained by sondes/satellite	Y	Emmons et al. (2010)
TM5	2.0° × 3.0°, L60	ECMWF-Int.	Modified CB05 scheme: 54 tracers, 104 gas-phase reactions. Stratosphere: O ₃ columns nudged to observations	Y	Williams et al. (2013) Huijnen et al. (2010)
TOMCAT	2.8° × 2.8°, L31	ECMWF-Int.	82 Tracers, 229 gas-phase reactions. Stratosphere: 2-D model used for boundary conditions	Y	Monks (2011) Chipperfield (2006)
WRF-Chem	100 and 50 km	WRF	MOZART-4 simulations used as boundary conditions	N	Grell et al. (2005) Fast et al. (2006)

Chemical and physical controls on pollution transport to the Arctic

S. A. Monks et al.

Figure 3. Taylor diagrams for Arctic surface comparisons of monthly mean time series of CO (left) and O₃ (right). Taylor diagrams show the extent to which models capture the observed variability (by the normalised standard deviation (NSD), shown by purple dashed contour), month-to-month changes in concentration (by the correlation (r), shown by green lines) and the mean model bias weighted by the monthly deviations from the annual mean (by the centered root-mean-square difference (RMSD), shown by the black dotted contours). Perfect agreement between a model and observations would result in a NSD of 1, a correlation of 1 and a RMSD of 0, which is indicated by “Observed” on the Taylor diagram. The letters represent the first letter of the station codes shown in Fig. 1.

Chemical and physical controls on pollution transport to the Arctic

S. A. Monks et al.

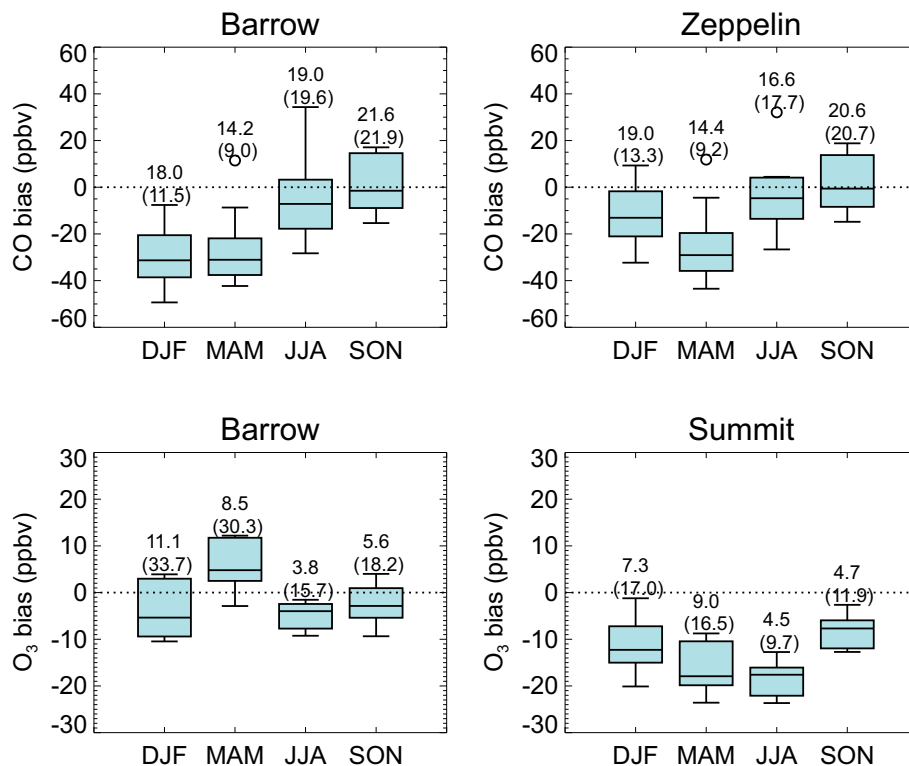

Figure 4. Box and whisker plots showing model seasonal biases (ppbv) for CO at Barrow and Zeppelin (top) and O₃ at Barrow and Summit (bottom). The box and whisker plots show the minimum, 25th percentile, median, 75th percentile and maximum values of the sample. The numbers on the plot represent the interquartile range of each sample (IQR = 75th–25th percentiles) in absolute concentrations and as a percent of observed concentrations (in brackets). Outliers which are more than 1.5 × IQR from the 25th or 75th percentiles are shown by circles.

Chemical and physical controls on pollution transport to the Arctic

S. A. Monks et al.

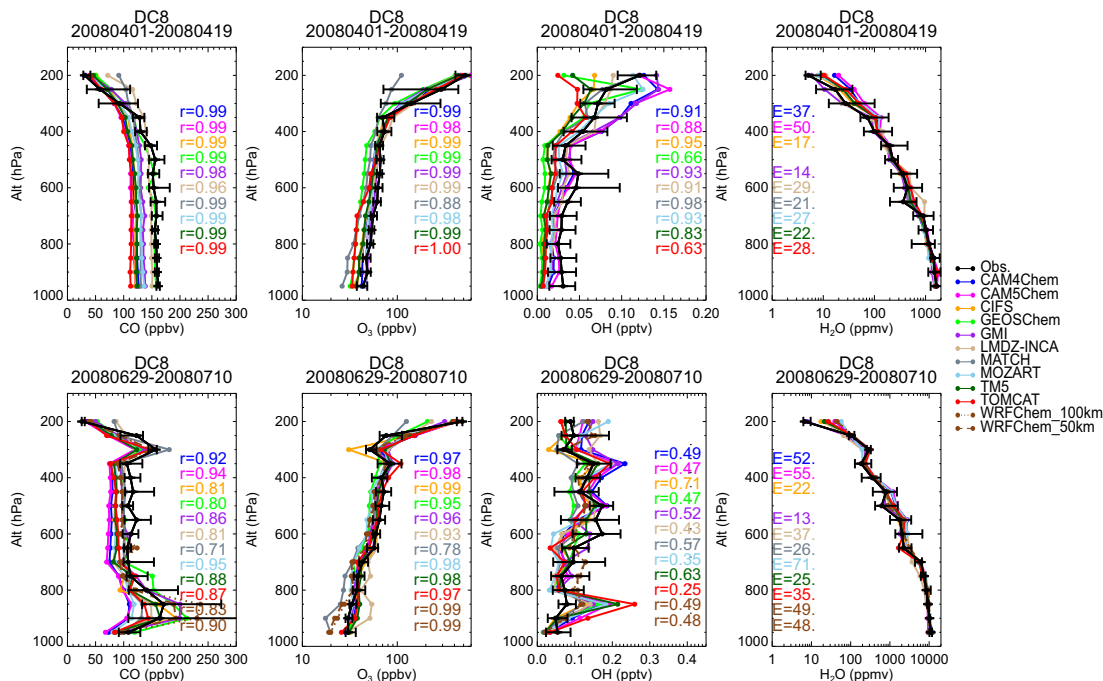

Figure 7. DC8 vertical profiles from the spring ARCTAS-A (top) and summer ARCTAS-B (bottom) campaigns in 2008. Median concentrations of CO (left), O₃ (middle), OH (middle) and H₂O (right), with error bars showing the 25th and 75th percentiles of the observations. Pearson's correlation coefficients are shown for CO, O₃ and OH. NMGE (%) is shown for H₂O. (N.B. Due to missing data in the GEOS-Chem hourly files the median concentrations in the 200, 250 and 300 hPa bins have been calculated over 463 data points instead of 678 data points which are used for the other models and observations.)

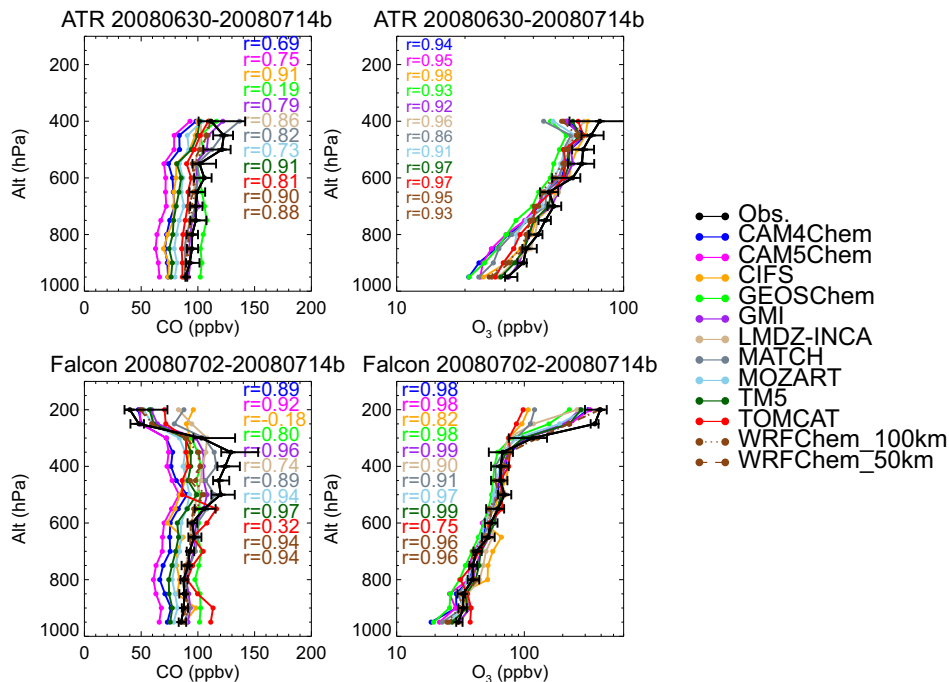

Figure 8. Vertical median profiles from the ATR-42 during the summer POLARCAT-France campaign (top) and the Falcon during the summer POLARCAT-GRACE campaign (bottom) for CO (left) and O₃ (right). Pearson's correlation coefficients are also shown. Error bars show the 25th and 75th percentiles of the observations.

Chemical and physical controls on pollution transport to the Arctic

S. A. Monks et al.

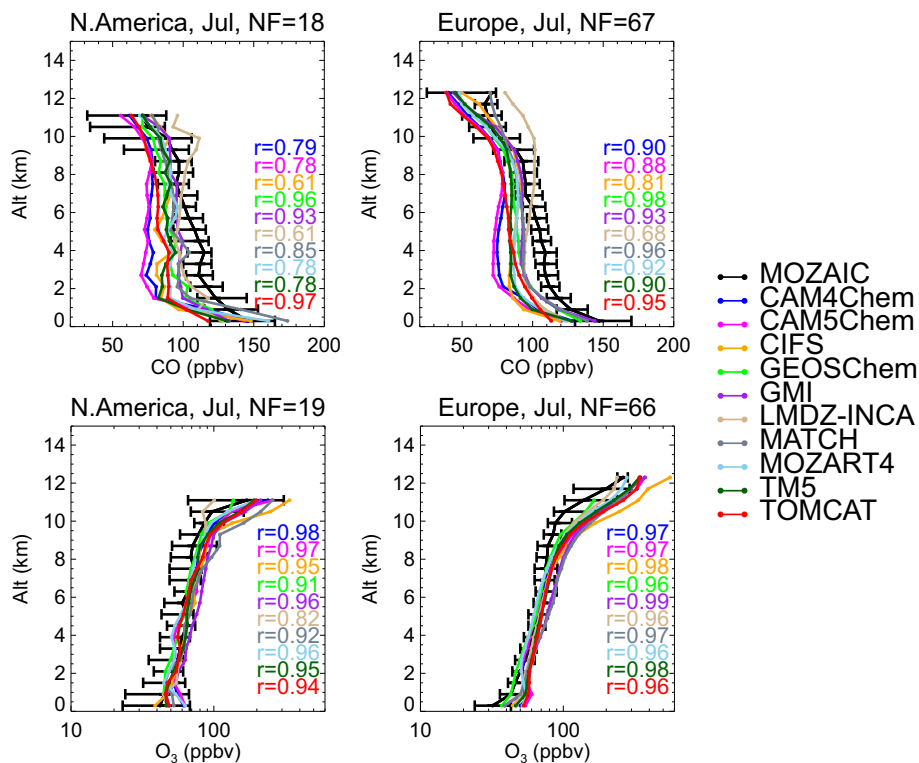

Figure 9. Vertical median profiles from the MOZIAIC aircraft project made between 18 June–14 July 2008, during ascent and descent in the regions of North America (left) and Europe (right). Observed CO (top) and O₃ (bottom) are compared to hourly simulated concentrations interpolated to MOZIAIC airport location. All data is put into 50 m bins and the error bars show the 25th and 75th percentiles of the observations in each bin. The number of profiles in each location used to calculate the regional profile averages are shown in Fig. 1.

Chemical and physical controls on pollution transport to the Arctic

S. A. Monks et al.

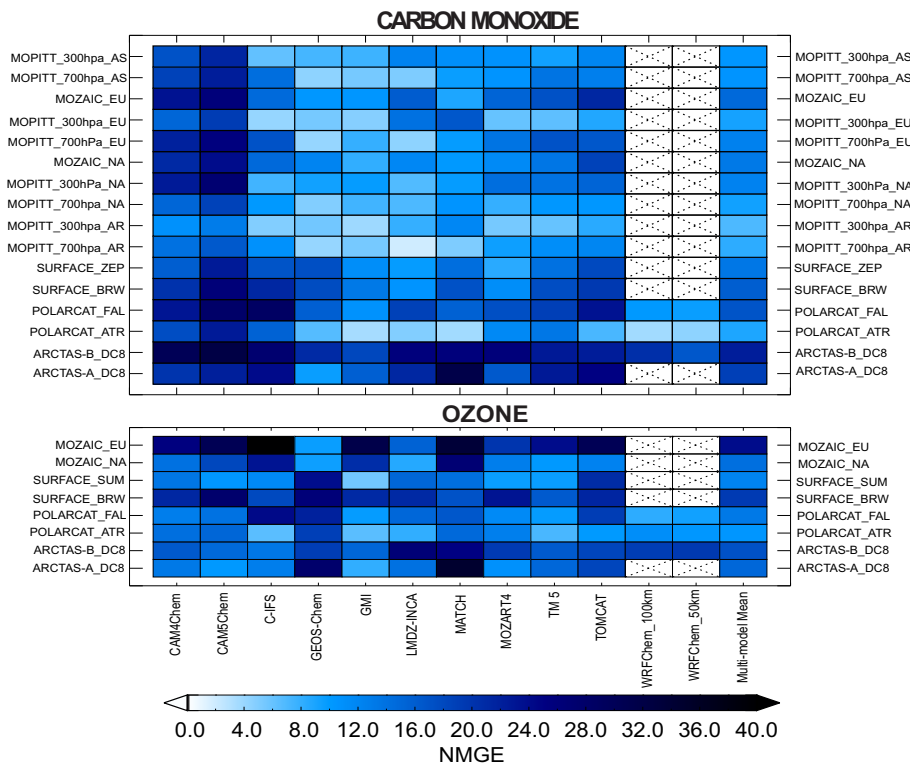

Figure 10. Summary of the Normalised Mean Gross Error ($NMGE = \frac{1}{N} \sum \left(\frac{|mod-obs|}{obs} \right) \times 100$) for all models against observations. The errors are shown for MOPITT regionally averaged satellite retrievals at 300 and 700 hPa (where, EU = Europe, NA = North America, AS = Asia, AR = Arctic), MOZAIC vertical profiles over source regions (where, EU = Europe, NA = North America), at surface sites (where, BRW = Barrow, ZEP = Zeppelin, SUM = Summit) and POLARCAT aircraft observations (where, FAL = Falcon).

Chemical and physical controls on pollution transport to the Arctic

S. A. Monks et al.

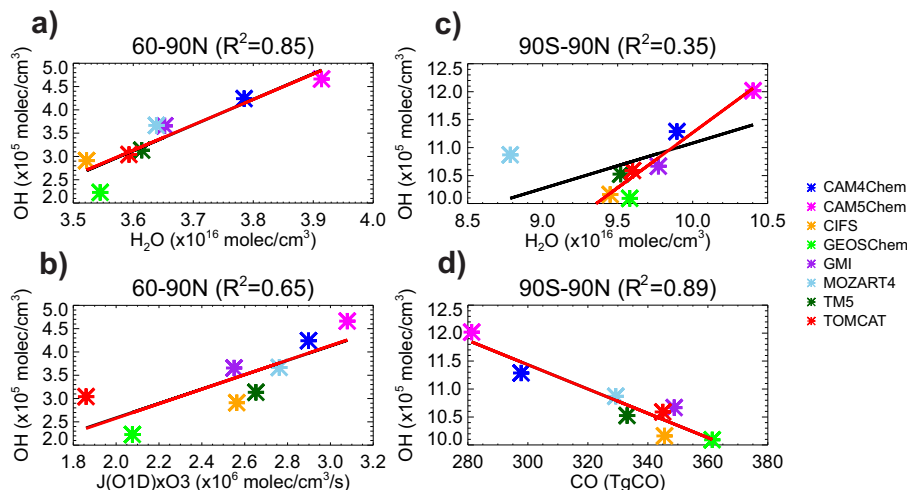

Figure 12. Annual mass-weighted tropospheric mean OH concentration as a function of the **(a)** annual mass-weighted mean water vapour concentration and **(b)** annual mass-weighted mean photolysis rates of $J(\text{O}^1\text{D})$ multiplied by O_3 concentrations in the Arctic, along with the annual mass-weighted global tropospheric mean OH concentration as a function of the **(c)** annual mass-weighted mean water vapour concentrations and **(d)** annual mean total tropospheric CO burden. The ordinary least squares (OLS) and the iteratively re-weighted least squares (IRLS) regression lines are shown in black and red, respectively. Correlations above 0.62 are significant at 90 % confidence level (CL) or above. Removing MOZART from analysis shown in **(b)** results in a r^2 value of 0.91, which is also significant above the 90 % CL. The troposphere has been selected according to the 150 ppbv O_3 contour, however, results are similar when using a climatological tropopause as described by Lawrence et al. (2001). The full list of regression coefficients **(b)** and coefficients of determination (r^2) are shown in Table S1.
