

**Reply to reviewers' comments on "Core and margin in warm convective clouds.
Part I: core types and evolution during a cloud's lifetime"**

Reply to reviewer #1:

General comment:

The authors have made considerable revisions to the manuscript, which have certainly improved it significantly. Nevertheless, I still feel there is a strong need to provide more physical insight into the simulations before the work can be published. I focus on this aspect in my reply, and leave most minor details for a later point.

General Answer:

We are glad the reviewer sees the revisions performed as an improvement to the paper and we would like to emphasize again and the goals of this work as described in the introduction: *"The differences between the cores' evolution in time shed new light on the competition of processes within a cloud in time and space. Moreover, such an understanding can serve as a guideline to all studies that perform the partition to cloud core and margin, and assist in determining the relevance of a given partition."*

Regarding physical insight, as opposed to most previous studies which either average over cloud lifetime or average together different cloud entities, our approach here yields information on cloud core development for all clouds in a cloud field for all their lifetimes. The result is a rich dataset which provides a comprehensive "map" of the cloud field. From this map the main in-cloud dynamical processes in play can also be deduced. We are aware that this approach has limitations as it does not describe each and every point within the cloud and therefore will not give a full description of the microphysics nor of the dynamics. However, it is our view that a full description of (for example) positive buoyancy fractions in all clouds in a cloud field has as much physical insight and importance as (for example) the mean buoyancy cross-section of all clouds.

That said, we have made an effort to add more analyses that address some of the questions raised by the reviewer. These include among others:

1. Quantitative information to describe the types of clouds in the CvM space, such as associating cloud properties with scatter size and adding percentages of different cloud types.
2. Added a section addressing the core-shell model, including analyses of in-cloud horizontal profiles of selected core parameters, which gives a more direct view of the inner-cloud dynamics at play (see details in SA1).
3. An objective analysis of the degree of interchangeability between different core types.

The reviewer raises many more suggestions regarding cloud dynamics, mass fluxes, and in-cloud circulations that would be of great interest to any reader in the field, but were not the research questions we set out to answer in this paper and we believe that such analyses deserve a work of their own and are beyond the scope of this paper.

Specific comments:

SC1) The authors state in their reply that the article focuses on a general comparison between the three core types for large statistics of clouds rather than on increasing understanding of core dynamics. I think a too strong focus on the statistics per se rather than the underlying physics and implications is not very fruitful. However, in putting more emphasis on the core-shell model the authors have provided a good starting point for further analysis. Still, I find it hard to square the results on the core-shell model here with previous studies, which do strongly point to the existence and influence of the shell. Compensating subsidence needs to take place somewhere, likely in the vicinity of the cloud, during the entire cloud life cycle and at all levels. One explanation may be in the fact that the shell is partially located in a non-cloudy area, and therefore not diagnosed in the current framework. For the 3D simulations, the irregular (fractal) shape of the cloud could also play a role.

It could indeed be that the static core-shell model has deficiencies, but is there an alternative model that performs better? For example, previous studies have suggested the warm and buoyant air is part of a vortex-ring, which may not occur at the center of the cloud. Does this hypothesis fit with the results from your simulations? The relative roles of this vortex ring circulation and evaporation in establishing the toroidal

circulation that forms which is mentioned in line 424 have not been fully worked out, as far as I know.

SA1) Indeed, the focus of the paper is not the core dynamics on a single cloud scale, however, we do not see this as a fault in the manuscript. In cloud fields which experience inherent large variability we claim that emergent behaviors from large statistics is as physically valuable as detailed analyses of single cloud dynamics. Regarding the core-shell model, following the reviewer's advice, we have revised the manuscript to examine in more details this model suitability to all 3 types of cloud's core. As is now summarized in the abstract: ***“For all three definitions, the core-shell model of a core (positive values) at the center of the cloud surrounded by a shell (negative values) at the cloud periphery applies to over 80% of a typical cloud's lifetime. The core-shell model is less appropriate in larger clouds with multiple cores displaced from the cloud center.”***. The revised manuscript deals with the in-cloud shape of the cores in greater depth (see Sect. 5.3 in revised manuscript– “Revisiting the core-shell model”). Three figures are now devoted to the question of location in the cloud and horizontal shape of the cores (see Figs. R1-R3 below that appear as Figs. 7-9 in the revised manuscript).

In Fig. R1 we show normalized distances between cloud centroid/COG and core centroid/COG. As written in the text: ***“For all core types, the large majority of clouds' cores are centered near the clouds' centroid or COG. Only less than 1% of the clouds' cores reside at the cloud edges, mostly seen for small dissipating clouds. Distances between cloud COG and core COG yield smaller values than for distances between centroids, implying that the mass is not equally distributed within the clouds and hence the centroid may be “missing” the true cloud center in terms of mass distribution.”***

Figure R2 shows the differences between single vs. multiple core clouds, and the effect it has on the normalized distance of the core COG from the cloud COG: ***“Further analysis shows that most clouds with $D_{norm,COG} > 0.2$ values can be attributed to the relatively larger sized clouds which typically contain multiple cores within them”***.

Finally, in Fig. R3 we observe the horizontal profiles of core parameters in clouds with no core or a single core: ***“For all core types, there are more single core (and no core) growing clouds (~55-57%) than dissipating clouds. Generally, it can be seen that the***

CS category profile is the most prevalent in clouds with single cores, ranging from a maximum of 66% of growing cloud Wcore profiles to a minimum of 26% of dissipating cloud Bcore profiles". It is also shown that the core-shell model applies to most clouds during the majority of their lifetime. However, we do point to the fact that the core-shell model may not apply to some subsets of clouds (i.e. large, multi-core clouds), especially during their dissipation stage.

Analyses of in-cloud circulations as suggested by the reviewer are non-trivial to perform for the large subset of various clouds within the cloud field. Again. Although we agree that it is interesting and important to perform such analyses, we believe it beyond the scope of this paper.

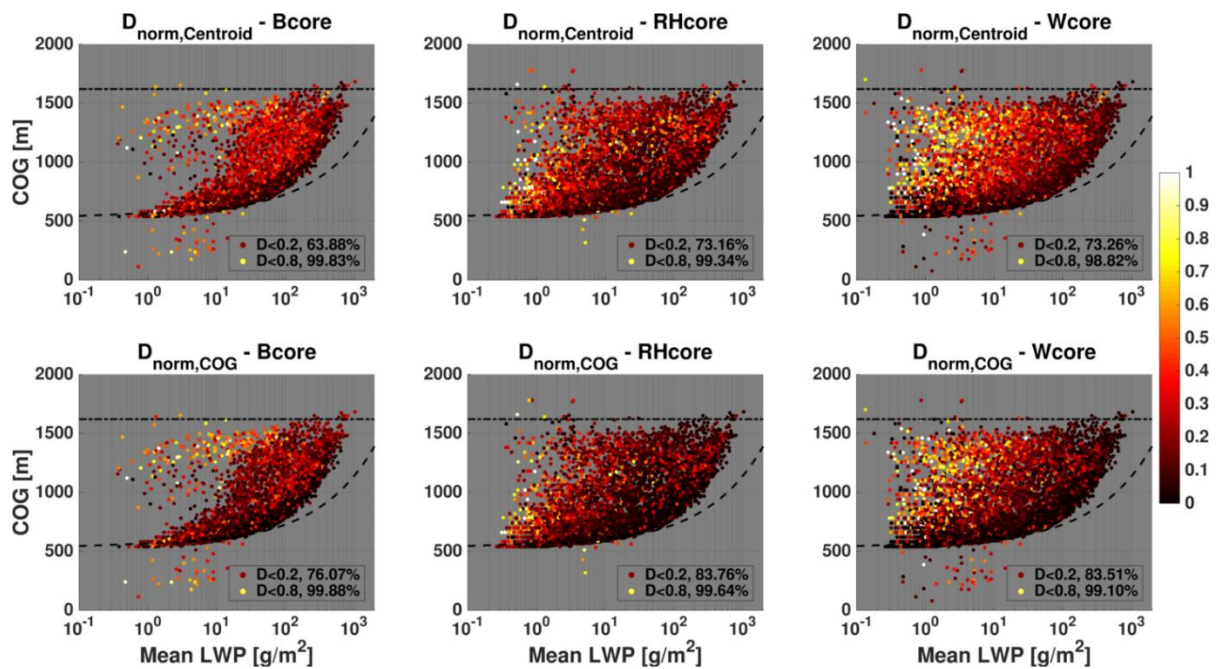

Figure R1 (Fig. 7 in the revised paper). CvM phase space diagrams of distances between core centroid and cloud centroid ($D_{norm,centroid}$, top panels), and distances between core COG and cloud COG ($D_{norm,COG}$, bottom panels) location, for the three different physical core types. The distances are normalized by the maximum distance between the cloud centroid/COG and the cloud perimeter. Bright (dark) colors indicates large (small) distances. Legends include percentage of points (out of the scatter) with D_{norm} below a certain threshold. As seen in Fig. 5, only clouds which contain a core fraction above zero (for the core in question) are considered.

Figure R2 (Fig. 8 in the revised paper). Same as Fig. 7, but for only distances between core COG and cloud COG ($D_{norm,COG}$). Scatter data is partitioned to clouds with a single core (top panels) and multiple cores (top panels). The size of each point in the scatter is proportional to the cloud mean area.

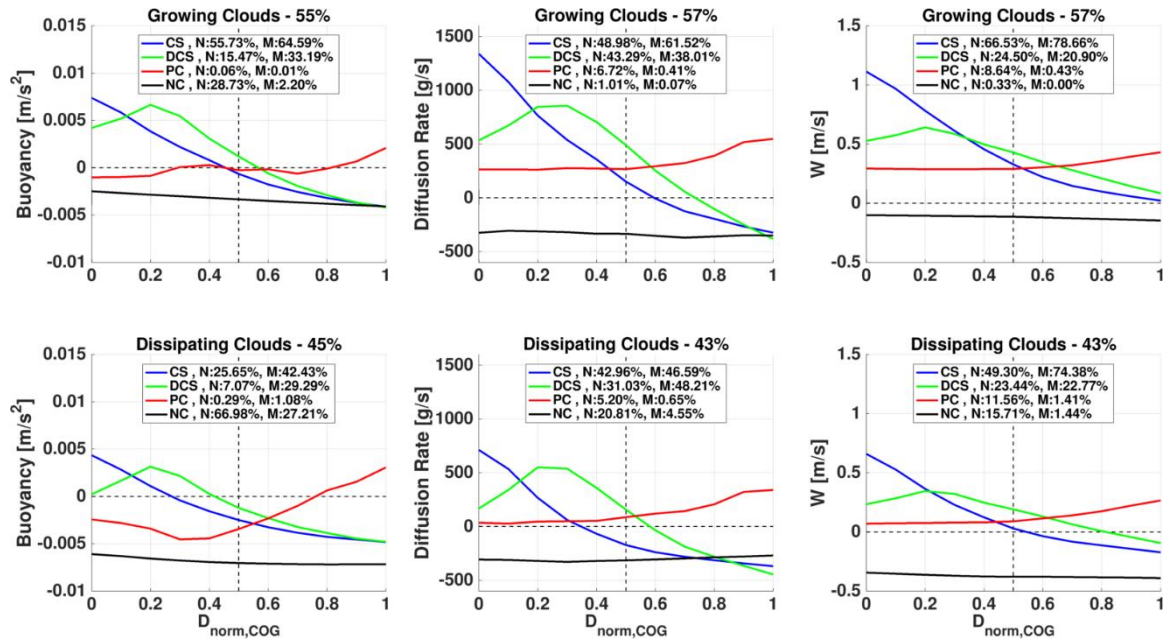

Figure R3 (Fig 9. in the revised paper). Mean horizontal profiles of core parameters from the cloud COG to cloud edge, for growing clouds (top) and dissipating clouds

(bottom), where the horizontal distances are normalized by the maximum distance to cloud edge. Parameters include buoyancy (left), diffusion rate (middle, taken as a proxy for the supersaturation core), and vertical velocity (right). The data is divided to profiles that match core-shell (CS), displaced core-shell (DCS), peripheral core (PC), or no core (NC) categories, as indicated by the different line colors. The percentage of cloud number (N) and cloud mass (M) attributed to each category are shown in the panel legends. We note that comparing the number percentages with mass percentages for each category gives an indication for the relative sizes of the clouds (e.g. higher $N\%$ than $M\%$ indicates smaller clouds).

SC2) One of the main questions in the new draft is whether the core definitions can be used interchangeably. This is a relevant question, which can help decide how to model clouds (see also W. Hannah, Entrainment versus dilution in tropical deep convection, JAS, 2017, this is a relevant article which I probably should have mentioned explicitly before). Since the buoyant cores are only a small part of the cloud, it may be argued they are really different from the other cores. What probably plays a role is that the largest part of the cloud is not relevant at all to mass, moisture and heat transport (though of course it is for radiative properties). The regions outside the buoyancy core carry hardly any net mass-flux and smaller perturbations of temperature and moisture content from the environment. This would be something worth analyzing: possibly, even some of the region identified as buoyant core here is only marginally buoyant and not contributing much to the various fluxes. Regions with both net condensation and positive buoyancy would be a further subset to look at.

SA2) As suggested by the reviewer, we have added an analysis regarding the degree of interchangeability between the different core definitions (see Fig. R4 below that appear as Fig. 6 in revised text). The figure displays the degree of interchangeability between core pairs, defined as follows: ***“To give an objective measure of the degree to which different core types can be used interchangeably, we define an interchangeable fraction (f_{int}), which is the multiplication of the two pixel fractions of a core pair (e.g. $f_{pixel_B \text{ in } RH} * f_{pixel_{RH \text{ in } B}}$).”*** Percentages of cloud which apply to a certain degree of interchangeability are added to the legends in the figure panels. Our findings are now

summarized in the abstract of the paper: “*The RHcore – Wcore pair is relatively most interchangeable, especially during the growing stages of the cloud*”.

In addition, we thank the reviewer for the suggested reference which was added to the text in the revised manuscript: “...*The cloud shell serves as a buffer between the core and the environment, and its extent is affected by, among others, environmental humidity, aerosol concentrations, and the magnitude and radius of the updraft creating the cloud (Dawe and Austin, 2011; Hannah, 2017; Seigel, 2014).* “. .

Figure R4 (Fig. 6 in the revised paper). CvM phase space diagrams of degree of interchangeability (f_{int}) for each of the core pairs (as indicated in the panel titles). Bright colors indicate high values (cores can be interchanged with little affect) while dark colors indicate small values (no overlap between cores). Only clouds with a core by at least one definition are considered. Scatter point size is proportional to the minimum f_{vol} of the core pairs in question. Panel legends include percentage of points (out of the scatter) with f_{int} above a certain threshold.

SC3) The authors have improved the connection to the literature regarding mixing and updraft dynamics. What is still missing is a discussion of previous work on the cloud life cycle and how this fits with the current results. In particular, the studies of Heus et al. (2009b) and Dawe and Austin (2013) already cited are relevant here. The work by Hannah also discusses the life cycle of clouds and the corresponding buoyant cores in detail.

SA3) Thank you for this important comment. We have added to the introduction a description of previous works dealing with a cloud life-cycle: “*It should be noted that*

previous works tracking clouds throughout their lifetime (e.g. (Dawe and Austin, 2012; Heiblum et al., 2016; Heus et al., 2009)) have reported multi-pulse core growth in cumulus clouds, where multiple buoyancy cores may initiate successively near the cloud base and fuel the cloud. However, these findings did not directly track the cores and were based mainly on the largest, most long-lived clouds.”

SC4) There is still a large emphasis on adiabatic theory. Although the authors admit it is simplistic, this is an understatement of the extent to which adiabatic theory fails to predict e.g. the vertical velocity and specific humidity in the cloud. It is really important to expand on the description of the role of mixing, dilution and drag. For example, in line 249, the authors write “The growing branch deviates from the adiabat at large masses depending on the degree of sub-adiabaticity of the cloud field.” This sounds a bit tautological and does not refer to the processes at play.

Another minor point where mixing comes into play is in line 252, where it is suggested that parcels could take the reverse trajectory in the CvM space. In a situation with realistic mixing, however, this could never occur as the resulting parcels would rapidly become positively buoyant again as they descend. I find the remarks on the sink term around line 405 confusing as well. Again, the role of mixing is key to the actual liquid water specific humidity.

SA4) In our view, although the adiabatic theory does not exactly predict the evolution of a whole cloud (due to mixing, dilution and drag processes, as listed by the reviewer), the adiabat serves as an intuitive reference for both the advanced and layman reader, and understanding of various cloud field characteristics can be gained from the comparison with it. The referred sentence explaining the adiabat has been modified to be clearer: “***The growing branch deviates from the adiabat at large masses depending on the degree of sub-adiabaticity of the cloud field (i.e. the degree of mixing between the cloud and its surrounding environment), which depends on its thermodynamic profile.***”. Nowhere in the paper do we try and explicitly solve or parameterize the vertical velocity in the cloud, hence we do not see the added value in further elaboration on mixing, dilution, and drag. For understanding the main processes at play in creating the differences between the cores we think that starting with the adiabatic theory is intuitive and helpful.

Regarding the reverse trajectory in the CvM space, it is important to note that the reverse trajectory is not that of a parcel but actually a trajectory in the CvM space, meaning the COG and mean LWP change in such a way that resembles a reverse trajectory. That said, we agree with the reviewer that the definition is not exact and thus have modified the text as follows: “*After or during the growth stage of clouds, they may undergo the following processes: i) dissipate via a quasi-reverse trajectory adjacent to the growing one, ii) dissipate via a gradual dissipation trajectory (magenta shade), iii) shed off small mass cloud fragments (red shades), iv) in the case of precipitating clouds, they can shed off cloud fragments in the sub-cloudy layer (grey shade).*”.

Finally, the purpose of Sect. 3.3 is set to be a simple one: “*Here we revisit the terms in Eq. 3 to explore an intuitive, first order understanding of the relation between vertical velocity core and the supersaturation core.*”, and thus the supersaturation eq. is a useful benchmark. Obviously, the actual conditions in the cloud are dependent on additional processes (more importantly mixing), but our goal is not to analytically solve the exact conditions in the clouds but rather have a general understanding of relations between cores.

SC5) Similarly, when the vertical velocity is discussed in the conclusions, drag is not even mentioned. For cumulus clouds, drag (and to some extent mixing) are crucial in much the same way drag is a first-order process when describing how a feather falls through air (gravity alone explains the direction of movement and sets an upper limit to the fall velocity, but the actual fall velocity of the feather is extremely poorly explained by gravity alone). The drag force is not analysed, and its potential role in setting the shape of the w-cores is not discussed at all.

SA5) Thank you for this comment. As noted above, many of the in-cloud dynamical characteristics (such as the evolution of the vertical velocity with height) are not explicitly analyzed and discussed. We note that the importance of the drag force is explained in the introduction of the manuscript, but that further conclusions of the effects of drag on the vertical velocity requires detailed analyses that are not the subject of this work, which is a comparison of the extents of the different core types at different stages of cloud’s lifetime.

SC6) One of the remarks about the time-scales of entrainment/mixing being of the order of seconds (line 339) is confusing in my opinion. Yes, these time-scales represent the mixing on the smallest scales, but this mixing would not occur without the entrainment of air into the cloud by larger-scale/longer time-scale eddies.

SA6) The section in question looks into the expected delay between changes in cloud buoyancy and consequential changes in cloud vertical velocity. In this scenario, a non-cloudy parcel has already been entrained into the cloud by a large eddy and evaporation starts. Based on this comment, in order to avoid confusion, we changed the remark on time-scales to refer only to the evaporation process: ***“Given an initial vertical velocity of ~ 0.5 m/s, the deceleration due to buoyancy (and reversal to negative vertical velocity) should occur within a typical time range of 1 - 10 minutes. These timescales are much longer than the typical timescales of evaporation (that eliminates the B_{core}) which range between 1 – 10 s (Lehmann et al., 2009).”***

SC7) I recognise there is value in the CvM diagrams used here. However, these contain many points and it is unclear which clouds actually contribute significantly to cloud volume or mass transport, as the (mean effective) radius of the cloud is factored out and only mean liquid water path is concerned. Possibly a selection of clouds could be shown, with point size proportional to radius. What is also unclear to me is how core fractions and centroids are determined once there are multiple cores in a single cloud. The shading in figure 4 needs a more precise definition in the text as well. Please make it clear in line 444 that mass refers to mass of the liquid phase.

SA7) We thank the reviewer for these comments. Although it is not a direct measure of mass transport, in Fig. 5 and 8 we have adjusted the scatter point sizes to be proportional to the mean cloud radius. In other figures we have adjusted scatter point size to give other information regarding volume fractions of cores. It is seen that cloud radius increases along the growing branch (with increase in mean LWP and COG) as expected. This analysis enables one to see that the larger sized clouds are more prone to larger buoyancy core fractions but smaller vertical velocity and supersaturation core fraction, as is now explained in the text: ***“We note that some of the largest clouds in the field (indicated by large scatter points) show higher (lower) B_{core} (RH_{core} , W_{core})***

volume fractions in comparison with smaller clouds located adjacent to them in the CvM phase space. Further analysis shows that these clouds are also precipitating to the surface“.

We now add an explanation to how the centroid/COG of a multiple core cloud is calculated in the text: ***“In case more than one core exists in a cloud, the mass (of each core) weighted location is taken to represent the core centroid or COG”***.

The shading in Fig. 4 is explained better in the revised text, as we added an explicit link between color and fraction: ***“In Fig. 4 the volume (f_{vol}) and mass (f_{mass}) fractions of the three core types are compared ... The color shades of the clouds indicate whether a cloud is mostly core (red – core fraction of 1), mostly margin (blue – core fraction 0), or equally divided to core and margin (white – core fraction 0.5). “***.

As suggested, the word *“liquid”* was added to the revised text: ***“Panels a and b show the core liquid mass (core mass / total mass - f_{mass}) and volume (core volume / total volume - f_{vol}) fractions out of the cloud's totals.”***.

SC8) The remarks in line 213-216 on thresholds and variance (of what?) are unclear to me.

SA8) Thank you for noticing this. The sentence was reformulated to be clearer: ***“Indeed, taking higher thresholds for the W_{core} (e.g. $W > 0.2 \text{ ms}^{-1}$) decreases the W_{core} extent in the cloud and reduces the variance of W_{core} fractions from different clouds in a cloud field (as seen in Fig. 4).”***

SC9) As far as I am concerned, the appendices are superfluous, as they demonstrate what previous studies have found already. This is particularly the case for the second appendix, which mostly shows that buoyancy mixes nearly linearly if two parcels are considered.

SA9) We agree with the reviewer that the findings in the appendices can be deduced from previous works, however, it is our view that they make the paper more complete and give a basic physical understanding to the results of the numerical model. For a non-expert reader not familiar with all the past literature, this may be very helpful.

SC10) It would also be good to go through the draft again and check for e.g. misplaced brackets, spelling/style issues, legend/colorbar placement in figures, the use of LWC rather than q_l and formatting of references.

SA10) Thank you for this comment, we have gone through the draft and corrected technical issues where found.

Reply to reviewer #2:

General comment:

After reading your revised manuscript and responses to reviewer comments, I find your manuscript to be much improved and nearly ready for acceptance. The paper seems more focused in its content and in what portions of the study are new and novel. Below I just have a few minor editorial things to be corrected that I noticed when reading through the paper.

General answer:

We are glad the reviewer found the paper much improved and thank the reviewer for the additional beneficial remarks and corrections.

Specific comments:

SC1) Line 263: Grammar to correct: "...interaction event if occurs."

SA1) Thank you, sentence was corrected to "...*an interaction event with another cloud*"

SC2) Line 331: Do the non-cloudy environmental parcels have any inherent positive or negative buoyancy that could be mixed into the cloud? How might this impact the analysis?

SA2) In the simplistic model we have chosen only two parcels are considered, a cloudy and non-cloudy one. Since buoyancy is a respective measure, the buoyancy of each parcel is calculated with respect to the parcel. Thus, positive (negative) cloudy parcel buoyancy implies negative (positive) non-cloudy parcel buoyancy. This of course is a great simplification of the conditions in a cloud field but it nevertheless helps illustrate the effects of mixing on buoyancy.

SC3) Line 387: Grammar to correct: "...should be no more larger...".

SA3) Thank you, the sentence was corrected to "*...should be no larger...*"

SC4) Line 544: Grammar to correct: "The decrease gradually with loss of cloud..."

SA4) Thank you, the sentence was corrected to: "*The fixel fractions decrease...*"

SC5) Line 764: Add space between "of" and "Bmargin".

SA5) Correction was carried out.

SC6) Figure 7 would still benefit from being larger. Fonts are very small and legend is difficult to read.

SA7) The figure and font sizes were increased for Fig. 7 (now Fig. 10).

Core and margin in warm convective clouds. Part I: core types and evolution during a cloud's lifetime

Abstract:

The properties of a warm convective cloud are determined by the competition between the growth and dissipation processes occurring within it. One way to observe and follow this competition is by partitioning the cloud to core and margin regions. Here we look at three core definitions: positive vertical velocity ($(W_{\text{core}}, W_{\text{core}})$), supersaturation ($(RH_{\text{core}}, RH_{\text{core}})$), and positive buoyancy ($(B_{\text{core}}, B_{\text{core}})$), and follow their evolution throughout the lifetime of warm convective clouds.

Using single cloud and cloud field simulations with bin-microphysics schemes, we show that the different core types tend to be subsets of one another in the following order: $B_{\text{core}} \subseteq RH_{\text{core}} \subseteq W_{\text{core}}$, $B_{\text{core}} \subseteq RH_{\text{core}} \subseteq W_{\text{core}}$. This property is seen for several different thermodynamic profile initializations, and is generally maintained during the growing and mature stages of a cloud's lifetime. This finding is in line with previous works and theoretical predictions showing that cumulus clouds may be dominated by negative buoyancy at certain stages of their lifetime. The $RH_{\text{core}} - W_{\text{core}}$ pair is most interchangeable, especially during the growing stages of the cloud.

~~During its mature and growth stage, the cloud and its~~ For all three definitions, the core-shell model of a core (positive values) at the center of the cloud surrounded by a shell (negative values) at the cloud periphery applies to over 80% of a typical cloud's lifetime. The core-shell model is less appropriate in larger clouds with multiple cores are displaced from the cloud center. Larger clouds may also exhibit buoyancy cores centered at a similar location near the cloud edge. During cloud dissipation the cores show less overlap, typically reduce in size, and may migrate from the cloud centroid. In some cases, buoyancy cores can reemerge and often reside at the cloud periphery. Thus, the core-shell model of a positively buoyant center surrounded by negatively buoyant shell only applies to a fraction of the cloud lifetime.

1. Introduction

Clouds are important players in the climate system (Trenberth et al., 2009), and currently constitute one of the largest uncertainties in climate and climate change research (IPCC, 2013). One of the reasons for this large uncertainty is the complexity created by opposing processes that occur at the same time but in different locations within a cloud. Although a cloud is generally considered as a single entity, physically, it can be partitioned to two main regions: i) a core region, where mainly cloud growth processes occur (i.e. condensation – accumulation of cloud mass), and ii) a margin region, where cloud suppression processes occur (i.e. evaporation - loss of cloud mass). Changes in thermodynamic or microphysical (aerosol) conditions impact the processes in both regions (sometimes in different ways), and thus the resultant total cloud properties (Dagan et al., 2015). To better understand cloud properties and their evolution in time, it is necessary to understand the interplay between physical processes within the core and margin regions (and the way they are affected by perturbations in the environmental conditions).

Considering convective clouds, there are several objective measures that have been used in previous works for separating a cloud's core from its margins (will be referred to as physical cores hereafter). In deep convective cloud simulations the core is usually defined by the updrafts' magnitude using a certain threshold, usually $W > 1 \text{ m}\cdot\text{s}^{-1}$ (Khairoutdinov et al., 2009; Kumar et al., 2015; Lebo and Seinfeld, 2011; Morrison, 2012). Studies on warm cumulus clouds have defined the clouds' core as parts with positive buoyancy and positive updrafts ([de Roode et al., 2012](#); Dawe and Austin, 2012; [de Roode et al., 2012](#); Heus and Jonker, 2008; Siebesma and Cuijpers, 1995) or solely regions with positively buoyancy (Heus and Seifert, 2013; Seigel, 2014). More recently, cloud partition to regions of supersaturation and sub-saturation has been used to define the cloud core in single cloud simulations (Dagan et al., 2015).

For simplicity, we focus on warm convective clouds (only contain liquid water), avoiding the additional complexity and uncertainties associated with mixed phase and ice phase microphysics. The common assumption when partitioning a convective cloud to its physical core and margin is that that the cloud core is at its geometrical center and the peripheral regions (i.e. edges) are the margin. Previous- observational (Heus et al., 2009a; Rodts et al., 2003; Wang et al., 2009) and numerical (Heus and Jonker, 2008;

Jonker et al., 2008; Seigel, 2014) works have studied the gradients of cloud thermodynamic properties from cloud center to edge, and suggest that a cloud is best described by a core-shell model. This model assumes a core with positive vertical velocity and buoyancy, surrounded by a shell with negative vertical velocity and buoyancy. The shell is the region where mixing between cloudy and environmental air parcels occurs, leading to evaporative cooling → decrease in buoyancy → decrease in vertical velocity. The cloud shell serves as a buffer between the core and the environment, and its extent is affected by, among others, environmental humidity, aerosol concentrations, and the magnitude and radius of the updraft creating the cloud (Dawe and Austin, 2011; Hannah, 2017; Seigel, 2014).

Based on previous findings, here we explore the partition of clouds to core and margin using three different objective core definitions where the cloud core threshold is set to be a positive value (of buoyancy, vertical velocity, or supersaturation). Cloud buoyancy (B) can be approximated by the following formula:

$$B = g \cdot \left(\frac{\theta'}{\theta_0} + 0.61q'_v - q_l \right) \quad (1),$$

Where θ_0 represents the reference state potential temperature, q_v is the water vapor mixing ratio, and q_l is the liquid water content. The ($'$) stands for the deviation from the reference state per height (Wang et al., 2009). Buoyancy is a measure for the vertical acceleration and its integral is the convective potential energy. Latent heat release during moist adiabatic ascent fuels positive buoyancy and clouds' growth, while evaporation and subsequent cooling drives cloud decay (Betts, 1973; de Roode, 2008; Betts, 1973). The prevalence of negatively buoyancy parcels at the cloud edges due to mixing and evaporation is a well-known phenomenon (Morrison, 2017). Mixing diagrams have been used to assess this effect (de Roode, 2008; Paluch, 1979; Taylor and Baker, 1991), and are at the root of convective parameterization schemes (Emanuel, 1991; Gregory and Rowntree, 1990; Kain and Fritsch, 1990) and parameterizations of entrainment and detrainment in cumulus clouds (de Rooy and Siebesma, 2008; Derbyshire et al., 2011).

Neglecting cases of air flow near obstacles or air mass fronts, buoyancy is the main source for vertical momentum in the cloud. In its simplest form, the vertical velocity (w) in the cloud can be approximated by the convective available potential energy

(CAPE) of the vertical column up to that height (Rennó and Ingersoll, 1996; Williams and Stanfill, 2002; Yano et al., 2005):

$$0.5w^2(h) = \int_{h_0}^h B(z) dz = CAPE(h) \quad (2).$$

Here we define CAPE to be the vertical integral of buoyancy from the lowest level of positive buoyancy (h_0 , initiation of vertical velocity) to an arbitrary top height (h). Usually, the CAPE serves as a theoretical upper limit, and the vertical velocity is smaller due to multiple effects (de Roode et al., 2012), most importantly the perturbation pressure gradient force (which oppose the air motion) and mixing with the environment (entrainment/detrainment) (de Roode et al., 2012; Morrison, 2016a; Peters, 2016). Recent studies have shown that entrainment effects on vertical velocity are of second order, and a rising thermal shows a balance between buoyancy and the perturbation pressure gradient (Hernandez-Deckers and Sherwood, 2016; Romps and Charn, 2015), the latter acting as a drag force on the updrafts. Nevertheless, initial updraft and environmental conditions play a crucial role in determining the magnitude of mixing effects on buoyancy, and thus also the vertical velocity profile in the cloud (Morrison, 2016a, 2016b, 2017).

The supersaturation (S , where $S=1$ is 100% relative humidity) core definition ($S-1>0$ or $RH>100\%$) partitions the cloud core and margin to areas of condensation and evaporation. Since we consider ~~nonconvective~~convective clouds, the only driver of supersaturation during cloud growth is upward vertical motion of air. Neglecting mixing with the environment, S and w can be linked as follows:

$$\frac{dS}{dt} = Q_1 w - Q_2 \frac{dq_l}{dt} \quad (3),$$

where Q_1, Q_2 are thermodynamic factors (Rogers and Yau, 1989). The thermodynamic factors are nearly insensitive to pressure for temperature above 0°C , and both weakly decrease (less than 15% net change) with temperature increase between 0°C and 30°C (Pinsky et al., 2013). The first term on the right-hand side is related to the change in the supersaturation due to adiabatic cooling or heating of the moist air (due to vertical motion). The second term is related to the change in the supersaturation due to condensation/evaporation of water vapor/drops. Hence, the supersaturation in a rising parcel depends on the magnitude of the updraft and on the condensation rate of vapor

to drops (a sink term). The latter is proportional to the concentration of aerosols in the cloud (Reutter et al., 2009; Seiki and Nakajima, 2014), which serve as cloud condensation nuclei (CCN) for cloud droplets. In Part II of this work we demonstrate some of the insights gained by investigating differences between the different cores properties and their time evolution when changing the aerosol loading.

The purpose of this part of the work (~~part~~Part I) is to compare and understand the differences between the three basic definitions of cloud core (i.e. W_{core} , RH_{core} , B_{core}) W_{core} , RH_{core} , B_{core}) throughout a convective cloud's lifetime, using both theoretical arguments and numerical simulations. Here, all simulated clouds are analyzed. It should be noted that the bin-microphysical schemes used here calculate saturation explicitly, by solving the diffusion growth equation, enabling super- and sub- saturation values in cloudy pixels. This is in contrary to many other works that used bulk-microphysical schemes which rely on saturation adjustment to 100% within the cloud (Khain et al., 2015). This difference may produce significant differences on the evolution of clouds and their cores. Specifically, we aim to answer questions such as:

- Which core type is largest? Which is smallest?
- How do the cores change during the lifetime of a cloud?
- Can different core types be used interchangeably without much effect on analysis results?
- Are the cores centered at the cloud's geometrical center, as expected from the core-shell model?

~~The differences between the cores' evolution in time shed new light on the competition of processes within a cloud in time and space. Moreover, such an understanding can serve as a guideline to all studies that perform the partition to cloud core and margin, and assist in determining the relevance of a given partition.~~

It should be noted that previous works tracking clouds throughout their lifetime (e.g. (Dawe and Austin, 2012; Heiblum et al., 2016a; Heus et al., 2009b) have reported multi-pulse core growth in cumulus clouds, where multiple buoyancy cores may initiate successively near the cloud base and fuel the cloud. However, these findings did not

directly track the cores and were based mainly on the largest, most long-lived clouds. The differences between the cores' evolution in time shed new light on the competition of processes within a cloud in time and space. Moreover, such an understanding can serve as a guideline to all studies that perform the partition to cloud core and margin, and assist in determining the relevance of a given partition.

2. Methods

2.1. Single cloud model

For single cloud simulations we use the Tel-Aviv University axisymmetric, non-hydrostatic, warm convective single cloud model (TAU-CM). It includes a detailed (explicit) treatment of warm cloud microphysical processes solved by the multi-moment bin method (Feingold et al., 1988, 1991; Tzivion et al., 1989, 1994). The warm microphysical processes included in the model are nucleation, diffusion (i.e. condensation and evaporation), collisional coalescence, breakup and sedimentation (for a more detailed description, see (Reisin et al., 1996)).

Convection was initiated using a thermal perturbation near the surface. A time step of 1 sec is chosen for dynamical computations, and 0.5 sec for the microphysical computations (e.g. condensation-evaporation). The total simulation time is 80 min. There are no radiation processes in the model. The domain size is 5x6 km, with an isotropic 50 m resolution. The model is initialized using a Hawaiian thermodynamic profile, based on the 91285 PHTO Hilo radiosonde at 00Z, 21 Aug, 2007. A typical oceanic size distribution of aerosols is chosen (Altaratz et al., 2008; Jaenicke, 1988), with a total concentration of 500 cm^{-3} . This concentration produced clouds that are non- to weakly- precipitating. In Part II additional aerosol concentrations are considered, including ones which produce heavy precipitation.

2.2. Cloud field model

Warm cumulus cloud fields are simulated using the System for Atmospheric Modeling (SAM) Model (version 6.10.3, for details see webpage: <http://rossby.msrc.sunysb.edu/~marat/SAM.html>) (Khairoutdinov and Randall, 2003)). SAM is a non-hydrostatic, anelastic model. Cyclic horizontal boundary conditions are

used together with damping of gravity waves and maintaining temperature and moisture gradients at the model top. An explicit Spectral Bin Microphysics (SBM) scheme (Khain et al., 2004) is used. The scheme solves the same warm microphysical processes as in the TAU-CM single cloud model, and uses an identical aerosol size distribution and concentration (i.e. 500 cm^{-3}) for the droplet activation process.

We use the BOMEX case study as our benchmark for shallow warm cumulus fields. This case simulates a trade-wind cumulus (TCu) cloud field based on observations made near Barbados during June 1969 (Holland and Rasmusson, 1973). This case study has a well-established initialization setup (sounding, surface fluxes, and surface roughness) and large scale forcing setup (Siebesma et al., 2003). It has been thoroughly tested in many previous studies (Grabowski and Jarecka, 2015; Heus et al., 2009b; Jiang and Feingold, 2006; Xue and Feingold, 2006). To check the robustness of the cloud field results, two additional case studies are simulated: (1) The same Hawaiian profile used to initiate the single cloud model, and (2) a continental shallow cumulus convection cases study (named CASS), based on long term observations taken at the ARM Southern Great Plains (SGP) site (Zhang et al., 2017).

The soundings, large scale forcing, and surface properties used to initialize the model are detailed in previous works (Heiblum et al., 2016a; Siebesma et al., 2003; Zhang et al., 2017). The domain size is 12.8 km x 12.8 km x 4 km for BOMEX, 12.8 km x 12.8 km x 5 km for Hawaii, and 25.6 km x 25.6 km x 16 km for CASS. The grid size is set to 100 m in the horizontal direction and 40 m in the vertical direction for all simulations. For CASS, above a height of 5 km the vertical grid size gradually increases to 1km. The time step for computation is 1 s for all simulations, with a total runtime of 8 hours for BOMEX and Hawaii, and 12 hours for CASS. The initial temperature perturbations (randomly chosen within $\pm 0.1^\circ\text{C}$) are applied near the surface, during the first time step.

2.3. Physical and Geometrical Core definitions

A cloudy pixel is defined here as a grid-box with liquid water amount that exceeds 0.01 g kg^{-1} . The physical core of the cloud is defined using three different definitions: 1)

$RH_{\text{core}}: RH_{\text{core}}$: all grid boxes for which the relative humidity (RH) exceeds $100\% + \%$

and condensation occurs, 2) B_{core} : buoyancy (see definition in Eq. (1)) above zero. The buoyancy is determined in each time step by comparing each cloudy pixel with the mean thermodynamic conditions for all non-cloudy pixels per vertical height, and 3) W_{core} : vertical velocity above zero. These definitions apply for both the single cloud and cloud field model simulations used here. We note that setting the core thresholds to positive values (>0) may increase the amount of non-convective pixels which are classified as part of a physical core, especially for the W_{core} . Indeed, taking higher thresholds for the W_{core} (e.g. $W > 0.2 \text{ ms}^{-1}$) decreases the W_{core} extent in the cloud and reduces the variance of W_{core} fractions between different clouds in a cloud field (as seen in Fig. 4). Nevertheless, any threshold taken is subjective in nature, while the positive vertical velocity definition is process based and objective.

The centroid (i.e. mean location in each of the axes) and center of gravity (i.e. cloud center of mass) are used here to represent the geometrical location of the total cloud (i.e. cloud geometrical core) and its specific physical cores. The distances between the total cloud and its cores' centroids (D_{norm}), as presented here, are normalized to cloud size to reflect the relative distance between the two centroids or COGs, where $D_{norm} = 0$ indicates coincident physical and geometrical cores and $D_{norm} = 1$ indicates a physical core located at the cloud boundary. In case more than one core exists in a cloud, D_{norm} is calculated for each of the cores, and then a mass weighted (for each core) mean D_{norm} is taken to represent the entire cloud. The single cloud simulations rely on an axisymmetric model and thus all centroids are horizontally located on the center axis while vertical deviations are permitted. For this model the distance is normalized by half the cloud's thickness. For the cloud field simulations both horizontal and vertical deviations are possible, therefore distances are normalized by the cloud's volume radius-maximum distance from the centroid/COG to a pixel at the cloud's edge.

2.4. Center of gravity vs. Mass (CvM) phase space

Recent studies (Heiblum et al., 2016a, 2016b) suggested the Center-of-Gravity vs. Mass (CvM) phase space as a useful approach to reduce the high dimensionality and to study results of large statistics of clouds during different stages of their lifetimes (such as seen

in cloud fields). In this space, the Center-of-Gravity (COG) height and mass of each cloud in the field at each output time step (taken here to be 1 min) are collected and projected in the CvM phase space. This enables a compact view of all clouds in the simulation during all stages of their lifetimes, with the main disadvantage being the loss of grid-size resolution information on in-cloud dynamical processes. Although the scatter of clouds in the CvM is sensitive to the microphysical and thermodynamic settings of the cloud field, it was shown that the different subspaces in the CvM space correspond to different cloud processes and stages (Heiblum et al., 2016a, 2016b). The lifetime of a cloud can be described by a trajectory on this phase space.

A schematic illustration of the CvM space ~~is~~ shown in Fig. 1. Most clouds are confined between the adiabat (curved dashed line) and the inversion layer base (horizontal dashed line). The adiabat curve corresponds to the theoretical evolution of a moist adiabat 1D cloud column in the CvM space. The large majority of clouds form within the growing branch (yellow shade) at the bottom left part of the space, adjacent to the adiabat. Clouds then follow the growing trajectory (grow in both COG and mass) to some maximal values. The growing branch deviates from the adiabat at large masses depending on the degree of sub-adiabaticity of the cloud field. (i.e. the degree of mixing between the cloud and its surrounding environment), which depends on its thermodynamic profile. After or during the growth stage of clouds, they may undergo the following processes: i) dissipate via a quasi-reverse trajectory ~~along~~adjacent to the growing one, ii) dissipate via a gradual dissipation trajectory (magenta shade), iii) shed off small mass cloud fragments (red shades), iv) in the case of precipitating clouds, they can shed off cloud fragments in the sub-cloudy layer (grey shade). The former two processes form continuous trajectories in the CvM space, while the latter two processes create disconnected subspaces.

2.5. Cloud tracking

To follow the evolution of individual clouds within a cloud field we use an automated 3D cloud tracking algorithm (see (Heiblum et al., 2016a) for details). It enables tracking of Continuous Cloud Entities (CCEs) from formation to dissipation, even if interactions between clouds (splitting or merging) occur during that lifetime. A CCE initiates as a new cloud forming in the field, and is tracked on the condition that it retains the majority

(>50%) of its mass during an interaction event ~~if-occurs-with another cloud~~. Thus, a CCE can terminate due to either cloud dissipation or cloud interactions.

3. Theoretical estimations for different core sizes

Here we propose simple physical considerations to evaluate the differences in cloud partition to core and margin using different definitions. The arguments rely on key findings from previous works (see Sect. 1) with aim to gain intuitive understanding of the potential differences between the core types. It is convenient to separate the analysis to an adiabatic case, and then add another layer of complexity and consider the effects of mixing of cloudy and non-cloudy air. In this theoretical derivation saturation adjustment to RH=100% is assumed for both cases, while in the other models used in this study, transient super- and sub-saturated cloudy parcels are treated (more realistic).

3.1. Adiabatic case – no mixing

Considering moist-adiabatic ascent, the excess vapor above saturation is instantaneously converted to liquid (saturation adjustment). Thus, the adiabatic cloud is saturated ($S=1$) throughout its vertical profile, and only W_{core} and B_{core} differences can be considered. It is assumed that the adiabatic convective cloud is initiated by positive buoyancy initiating from the sub-cloudy layer. As long as the cloud is growing it should have positive CAPE and will experience positive w throughout the column even if the local buoyancy at specific height is negative. Eventually the cloud must decelerate due to negative buoyancy and reach a top height, where CAPE = 0 and $w = 0$. Hence, for the adiabatic column case, B_{core} is always a proper subset of W_{core} ($B_{core} \subset W_{core}$). W_{core} (i.e. $B_{core} \subset W_{core}$). These effects are commonly seen in warm convective cloud fields where permanent vertical layers of negative buoyancy (but with updrafts) within clouds typically exist at the bottom and top regions of the cloudy layer (Betts, 1973; de Roode and Bretherton, 2003; Betts, 1973; Garstang and Betts, 1974; Grant and Lock, 2004; Heus et al., 2009b; Neggers et al., 2007).

3.2. Cloud parcel entrainment model

A mixing model between a saturated (cloudy) parcel and a dry (environment) parcel is used to illustrate the effects of mixing on the different core types. The details of these theoretical calculations are shown in Appendix A. The initial cloudy parcel is assumed to be saturated (part of $\overline{RH_{core}}$, $\overline{RH_{core}}$), have positive vertical velocity (part of $\overline{W_{core}}$, $\overline{W_{core}}$), and experience either positive or negative buoyancy (part of $\overline{B_{core}}$ or $\overline{B_{margin}}$, $\overline{B_{core}}$ or $\overline{B_{margin}}$), as is seen for the adiabatic column case. Additionally, mixing is assumed to be isobaric, and in a steady environment where the average temperature of the environment per a given height does not change. The resultant mixed parcel will have lower humidity content and lower LWC as compared to the initial cloudy parcel, and a new temperature. In nearly all cases (beside in an extremely humid environment) the mixed parcel will be sub-saturated and evaporation of LWC will occur. Evaporation ceases when equilibrium is reached due to air saturation ($S=1$) or due to complete evaporation of the droplets (which means $S<1$, and the mixed parcel is no longer cloudy since it has no liquid water content).

In addition to mixing between cloudy (core or margin) and non-cloudy parcels, mixing between core and margin parcels (within the cloud) also occurs. This mixing process can be considered as “entrainment-like” with respect to the cloud core. Considering the changes in the $\overline{W_{core}}$, $\overline{W_{core}}$ and $\overline{RH_{core}}$, $\overline{RH_{core}}$, there is no fundamental difference in the treatment of mixing of cloudy and non-cloudy parcels, or mixing between core and margin (because the margins and the environment are typically sub-saturated and experience negative vertical velocity). However, for the changes in the $\overline{B_{core}}$, $\overline{B_{core}}$ after mixing, there exists a fundamental difference between mixing *with* the reference temperature/humidity state (in the case of mixing with the environment) and mixing *given* a reference temperature/humidity state (in mixing between $\overline{B_{core}}$, $\overline{B_{core}}$ and $\overline{B_{margin}}$, $\overline{B_{margin}}$). Thus, it is interesting to check the effects of mixing between $\overline{B_{core}}$, $\overline{B_{core}}$ and $\overline{B_{margin}}$, $\overline{B_{margin}}$ parcels on the total extent of the $\overline{B_{core}}$, $\overline{B_{core}}$ with respect to the other two core types. The details of this second case are shown in Appendix B.

3.2.1. Effects of non-cloudy entrainment on buoyancy

When mixed with non-cloudy air, the change in buoyancy of the initial cloudy parcel (which is a part of $W_{core}W_{core}$ and $RH_{core}RH_{core}$ and either $B_{core}B_{core}$ or $B_{margin}B_{margin}$) happens due to both mixing and evaporation processes. The theoretical calculations show that for all relevant temperatures ($\sim 0^{\circ}\text{C}$ to 30°C , representing warm Cu), the change in the parcel's buoyancy due to evaporation alone will always be negative (see appendix A). It is because the negative effect of the temperature decrease outweighs the positive effects of the humidity increase and water loading decrease. Nevertheless, the total change in the buoyancy (due to both mixing and evaporation) depends on the initial temperature, relative humidity, and liquid water content of the cloudy and non-cloudy parcels.

In Fig. A1 a wide range of non-cloudy environmental parcels, each with their own thermodynamic conditions, are mixed with a saturated cloud parcel with either positive or negative buoyancy. The main conclusions regarding the effects of such mixing on the buoyancy are as follows:

- i. To a first order, the initial buoyancy values are temperature dependent, where a cloudy parcel that is warmer (colder) by more than $\sim 0.2^{\circ}\text{C}$ than the environment will be positively (negatively) buoyant for common values of cloudy layer environment relative humidity ($\text{RH} > 80\%$).
- ii. Parcels that are initially part of $B_{core}B_{core}$ may only lower their buoyancy due to entrainment, either to positive or negative values depending on the environmental conditions.
- iii. The lower the environmental RH, the larger the probability for parcel transition from $B_{core}B_{core}$ to $B_{margin}B_{margin}$ after entrainment.
- iv. Parcels that are initially part of $B_{margin}B_{margin}$ can either increase or decrease their buoyancy value, but never become positively buoyant. The former case (buoyancy decrease) is expected to be more prevalent since it occurs for the smaller range of temperature differences with the environment.

In summary, entrainment is expected to always have a net negative effect on $B_{core}B_{core}$ extent and $B_{margin}B_{margin}$ values, while evaporation feedbacks serve to maintain

RH_{core} RH_{core} in the cloud. Thus, we can predict that B_{core} B_{core} should be a subset of RH_{core} RH_{core} (i.e. $B_{core} \subseteq RH_{core}$). $B_{core} \subseteq RH_{core}$).

3.2.2. Effects of core and margin mixing on buoyancy

We consider the case of mixing between the B_{core} B_{core} and B_{margin} B_{margin} meaning positively buoyant and negatively buoyant cloud parcels. For simplicity, we assume both parcels are saturated ($S=1$, both included in the RH_{core} RH_{core}). As seen above, such conditions exist in both the adiabatic case and in the case where an adiabatic cloud has undergone some entrainment with the environment. The buoyancy differences between the saturated parcels are mainly due to temperature differences, but also due to the increasing saturation vapor pressure with increasing temperature (see Appendix B for details).

In Fig. B1 is it shown that the resultant mixed parcel's buoyancy can be either positive or negative, depending on the magnitude of temperature difference of each parcel (core or margin) from that of the environment. However, in all cases the mixed parcel is supersaturated. This result can be generalized: given two parcels with equal RH but different temperature, the RH of the mixed parcel is always equal or higher than the initial value. Hence, B_{core} B_{core} can either increase or decrease in extent, while the RH_{core} RH_{core} can only increase due to mixing between saturated B_{core} B_{core} and B_{margin} B_{margin} parcels. This again strengthens the assumption that B_{core} B_{core} should be a subset of RH_{core} RH_{core} .

We note that an alternative option for mixing between the core and margin parcels that exist here, where either or both of the parcels are subsaturated so that the mixed parcel is subsaturated as well. In this case evaporation will also occur. As seen in Appendix A, this should further reduce the buoyancy value of the mixed parcel (while increasing the RH).

3.2.3. Effects of entrainment on vertical velocity

The vertical velocity equation dictates that buoyancy is the main production term (de Roode et al., 2012; Romps and Charn, 2015), and is balanced by perturbation pressure gradients and mixing (on grid and sub-grid scales). Thus, all changes of magnitude (and sign) in vertical velocity should lag the changes in buoyancy. This is the basis of convective overshooting and cumulus formation in the transition layer (see Sect. 3.1). It is interesting to assess the magnitude of this effect by quantifying the expected time lag between buoyancy and vertical velocity changes. The calculations in Appendix A indicates negative buoyancy values reaching -0.1 m/s^2 due to entrainment. However, measurements from within clouds show that the temperature deficiency of cloudy parcels with respect to the environment is generally restricted to less than 1°C for cumulus clouds (Burnet and Brenguier, 2010; Malkus, 1957; Sinkevich and Lawson, 2005; Wei et al., 1998), and thus the negative buoyancy should be no ~~more~~ larger than -0.05 m/s^2 . This value is closer to current and previous simulations and also observations that show negative buoyancy values within clouds to be confined between -0.001 and -0.01 m/s^2 ([Ackerman, 1956](#); de Roode et al., 2012; ~~Aekerman, 1956~~).

Given an initial vertical velocity of $\sim 0.5 \text{ m/s}$, the deceleration due to buoyancy (and reversal to negative vertical velocity) should occur within a typical time range of 1 - 10 minutes. These timescales are much longer than the typical timescales of ~~entrainment (mixing and evaporation (that eliminate~~eliminates the ~~B_{core}~~) B_{core}) which range between 1 – 10 s (Lehmann et al., 2009). Moreover, the fact that a drag force typically balances the buoyancy acceleration (Romps and Charn, 2015) can also contribute to a time lag between effects on buoyancy and subsequent effects on vertical velocity. Therefore, the switching of sign for vertical velocity should occur with substantial delay compared to the reduction of buoyancy, and ~~B_{core}~~ B_{core} should be a subset of ~~W_{core}~~ W_{core} (i.e. ~~$B_{\text{core}} \subseteq W_{\text{core}}$~~) $B_{\text{core}} \subseteq W_{\text{core}}$) during the growing and mature stages of a cloud's lifetime.

3.3. The relation between supersaturation and vertical velocity cores

Here we revisit the terms in Eq. [3.3](#) to explore an intuitive, first order understanding of [the relation between vertical velocity core and the supersaturation core](#). A rising parcel initially has no liquid water content, with its only source of supersaturation being the updraft w , and thus initially the ~~RH_{core}~~ RH_{core} should always be a subset of ~~W_{core}~~ W_{core} .

W_{core}. In general, since the sink term $\frac{\partial LWG}{\partial t} \frac{dq_1}{dt}$ becomes a source only when $S < 1$ (the condition for evaporation), the only way for a convective cloud to produce supersaturation (i.e. $S > 1$) is by updrafts during all stages of its lifetime. Once supersaturation is achieved, the sink term becomes positive $\frac{\partial LWG}{\partial t} \frac{dq_1}{dt} > 0$ and balances the updraft source term, so that supersaturation either increases or decreases. At any stage, if downdrafts replace the updrafts within a supersaturated parcel, the consequent change in supersaturation becomes strictly negative (i.e. $\frac{dS}{dt} < 0$). This negative feedback limits the possibility to find supersaturated cloudy parcels with downdrafts. Hence, we can expect the RH_{core} to be smaller than W_{core} during the majority of a cloud's lifetime.

4. Results - Single cloud simulation

The differences between the three types of core definitions are examined during the lifetime of a single cloud (Fig. 2), based on the Hawaiian profile. The cloud's total lifetime is 36 minutes (between $t=7$ and $t=43$ min of simulation). Each panel in Fig. 2 presents vertical cross-sections of the three cores (magenta - W_{core}, green - RH_{core}, and yellow - B_{core}) at four points in time (with 10-minute intervals). The cloud has an initial cloud base at 850m, and grows to a maximal top height of 2050 m. The condensation rates (red shades) increase toward the cloud center and the evaporation rates (blue shades) increase toward the cloud edges. Evaporation at the cloud top results in a large eddy below it that contributes to mixing and evaporation at the lateral boundaries of the cloud. Thus, a positive feedback is initiated which leads to cooling, negative buoyancy, and downdrafts. The dissipation of the cloud is accompanied with a rising cloud base and lowering of the cloud top.

During the growing stage ($t=10, 20$ min), when substantial condensation still occurs within the cloud, all of the cores seem to be self-contained within one another, with B_{core} being the smallest and W_{core} being the largest. During the final dissipation stages, when the cloud shows only evaporation ($t=40$), W_{core} and RH_{core} disappear while there is still a small B_{core} near the cloud top. Further analysis (see Part II) shows that the entire dissipating cloud is colder and more

humid than the environment but downdrafts from the cloud top (see arrows in Fig. 2) promote ~~adiabatic~~ heating, and by that increase the buoyancy in dissipating cloudy pixels, sometimes reaching positive values. These buoyant pockets will be discussed further in Part II. The results indicate that the three types of physical cores of the cloud are not located around the cloud's geometrical core along the whole cloud lifetime. During cloud growth (i.e. (increase in mass and size) the three types of cores surround the cloud's center, while during late dissipation the B_{core} is at offset from the cloud center.

For a more complete view of the evolution of the three core types in the single cloud case, time series of core fractions are shown in Fig. 3. Panels a and b show the core liquid mass (core mass / total mass - f_{mass}) and volume (core volume / total volume - f_{vol}) fractions out of the cloud's totals. The results are similar for both measures except for the fact that core mass fractions are larger than core volume fractions. This is due to significantly higher LWC per pixel in the cores compared to the margins, which skews the core mass fraction to higher values. Core mass fractions during the main cloud growing stage (between $t=7$ and $t=27$ min simulation time) are around 0.7 - 0.85 and core volume fractions are around 0.5 - 0.7. The time series show that as opposed to the W_{core} and RH_{core} fractions which decrease monotonically with time, B_{core} shows a slight increase during stages of cloud growth. In addition, for most of the cloud's lifetime the B_{core} fractions are the smallest and the W_{core} fractions are the largest, except for the final stage of the clouds dissipation where downdrafts from the cloud top creates pockets of positive buoyancy. These pockets are located at the cloud's peripheral regions rather than near the cloud's geometrical center as is typically expected for the cloud's core. In the cloud's center (the geometrical core) the B_{core} is the first one to terminate (at $t=32$ min) compared to both W_{core} and RH_{core} that decay together (at 36 min).

For describing the locations of the physical cores, we examine the normalized distances (D_{norm}) between the cloud's centroid and the cores' centroids. The evolution of these distances is shown in Fig. 3c. At cloud initiation ($t=7$ min), when the cloud is very small, all cores' centroids coincide with the total cloud centroid location. The B_{core} (and RH_{core} to a much lesser degree) centroid then deviates from the cloud centroid to a normalized distance of 0.27 ($t=8$ min). As cloud growth

proceeds, $B_{\text{core}}B_{\text{core}}$ grows and its centroid coincides with the cloud's centroid. All cores' centroids are located near the cloud centroid during the majority of the growing and mature stages of the cloud, showing normalized distances <0.1 . During dissipation ($t > 27$ min), the cores' centroid locations start to distance away from the cloud's geometrical core followed by a reduction in distances due to the rapid loss of cloud volume. As mentioned above, it is shown that the regeneration of positive buoyancy at the end of cloud dissipation ($t = 40$ min) takes place at the cloud edges, with normalized distance >0.5 .

Finally, in Fig. 3d the fraction of pixels of each core contained within another core is shown. It can be seen that for the majority of cloud lifetime (up to $t = 33$ min) $B_{\text{core}}B_{\text{core}}$ is subset (pixel fraction of 1) of $RH_{\text{core}}, RH_{\text{core}}$, and the latter is a subset of $W_{\text{core}}, W_{\text{core}}$. As expected, the other three permutations of pixel fractions (e.g. $W_{\text{core}}W_{\text{core}}$ in $B_{\text{core}}B_{\text{core}}$) show much lower values. The cloudy regions that are not included within $B_{\text{core}}B_{\text{core}}$ but are included within the two other cores are exclusively at the cloud's boundaries (see Fig. 2). The same pattern is seen for cloudy regions that are included within $W_{\text{core}}W_{\text{core}}$ but not in $RH_{\text{core}}, RH_{\text{core}}$. During the dissipation stage of the cloud its core subset property (i.e. $B_{\text{core}} \subseteq RH_{\text{core}} \subseteq W_{\text{core}} \Rightarrow B_{\text{core}} \subseteq RH_{\text{core}} \subseteq W_{\text{core}}$) breaks down. Similar temporal evolutions as shown here are seen for the other simulated clouds (with various aerosol concentrations) in part II of this work.

5. Results - Cloud field simulations

5.1. Partition to different core types

To test the robustness of the observed behaviors seen for a single cloud, it is necessary to check whether they also apply to large statistics of clouds in a cloud field. The BOMEX simulation is taken for the analyses here. We discard the first 3 hours of cloud field data, during which the field spins-up and its mean properties are unstable. In Fig. 4 the volume (f_{vol}) and mass (f_{mass}) fractions of the three core types are compared for all clouds (at all output times – every 1 min) in the CvM space. As seen in Fig. 1, the location of specific clouds in the CvM space indicates their stage in evolution. Most clouds are confined to the region between the adiabat and the inversion layer base except for small precipitating (lower left region) and dissipating clouds (upper left

region). The color shades of the clouds indicate whether a cloud is mostly core (red); mostly – core fraction 1), all margin (blue – core fraction 0), or equally divided to core and margin (white); – core fraction 0.5). The size of each point in the scatter is proportional to the cloud’s mean horizontal cross-sectional area. A general increase in mean cloud area with increase in mean cloud LWP is seen (i.e. synchronous growth in horizontal and vertical axis).

As seen for the single cloud, the core mass fractions tend to be larger than core volume fractions, for all core types. This is due to the fact that LWC values in the cloud core regions are higher than in margin regions, so that a cloud might be core dominated in terms of mass while being margin dominated in terms of volume. Focusing on the differences between core types, the color patterns in the CvM space imply that B_{core} definition yields the lowest core fractions (for both mass and volume), followed by RH_{core} with higher values and W_{core} with the highest values. The absence of the B_{core} is especially noticeable for small clouds in their initial growth stages after formation (COG ~ 550 m and LWP < 1 g m⁻²). Those same clouds show the highest core fractions for the other two core definitions. This large difference can be explained by the existence of the transition layer (as discussed in Sect. 3) near the lifting condensation level (LCL) in warm convective cloud fields which is the approximated height of a convective cloud base (Craven et al., 2002; Meerkötter and Bugliaro, 2009). Within this layer parcels rising from the sub-cloudy layer are generally colder than parcels subsiding from the cloudy layer. Thus, this transition layer clearly marks the lower edge of the buoyancy core as most convective clouds are initially negatively buoyant.

Generally, the growing cloud branch (i.e. the CvM region closest to the adiabat) shows the highest core fractions. The RH_{core} and W_{core} fractions decrease with cloud growth (increase in mass and COG height) while the B_{core} initially increases, shows the highest fraction values around the middle region of the growing branch and then decreases for the largest clouds. The transition from the growing branch to the dissipation branch is manifested by a transition from core dominated to margin dominated clouds (i.e. transition from red to blue shades). Mixed within the margin dominated dissipating cloud branch, a scatter of W_{core} dominated small clouds can be seen as well. These represent cloud fragments which shed off large clouds during

their growing stages with positive vertical velocity. They are sometimes RH_{core} -RHcore dominated as well but are strictly negatively buoyant. The few precipitating cloud fragments seen for this simulation (cloud scatter located below the adiabat) tend to be margin dominated, especially for the RH_{core} -RHcore.

The percentages in the panel legends (Fig. 4) indicate the fraction of clouds (out of the scatter) which are core dominated with respect to volume or mass. Only ~2% of clouds are dominated by Bcore in terms of cloud volume but more than 45% of the clouds have the majority of their mass within the Bcore region. These numbers increase considerably for the RHcore (Wcore), where 44% (80%) of the clouds are core dominated with respect to cloud volume and 85% (87%) of the clouds are core dominated with respect to cloud mass. Thus, the Bcore can be considered to take up a small portion of a typical cloud mass and volume while the Wcore generally occupies most of the cloud. We note that some of the largest clouds in the field (indicated by large scatter points) show higher (lower) Bcore (RHcore, Wcore) volume fractions in comparison with smaller clouds located adjacent to them in the CvM phase space. Further analysis shows that these clouds are also precipitating to the surface. The increase of Bcore fractions in precipitating clouds is discussed in Part II of this work.

5.2. Subset properties of cores

From Fig. 4 it is clear that W_{core} -Wcore tends to be the largest and B_{core} -Bcore tends to be the smallest. To what degree however, are the cores subsets of one another as was seen for the single cloud simulation? ~~It is also interesting to check whether the different physical cores are centered near the cloud's geometrical core.~~ In Fig. 5 the pixel fraction (f_{pixel}) of each core type within another core type is shown for all clouds in the CvM space. A f_{pixel} of 1 (bright colors) indicates that the pixels of the specific core in question (labeled in each panel title) are a subset of the other core (also labeled in the panel title) and a f_{pixel} of 0 (dark colors) indicates no intersection between the two cores in the cloud. It is seen that B_{core} tends to be a subset of both other cores, with f_{pixel} around 0.75-1 for most of the growing branch area and large mass dissipating clouds which still have some positive buoyancy. The pixel fractions are higher for B_{core} -Bcore inside W_{core} -Wcore compared with B_{core} -Bcore inside RH_{core} -RHcore, but

both show decrease with increase in growing branch cloud mass, meaning the chance for finding a proper subset $B_{\text{core}} \subseteq B_{\text{core}}$ decreases in large clouds.

The CvM space of $RH_{\text{core}} \subseteq RH_{\text{core}}$ inside $W_{\text{core}} \subseteq W_{\text{core}}$ shows an even stronger relation between these two core types. For almost all growing branch clouds, the $RH_{\text{core}} \subseteq RH_{\text{core}}$ is a subset of $W_{\text{core}} \subseteq W_{\text{core}}$ (i.e. $RH_{\text{core}} \subseteq W_{\text{core}}$). The $RH_{\text{core}} \subseteq W_{\text{core}}$ fractions tend to decrease gradually with loss of cloud mass in the dissipation branch. However, some small dissipating clouds show $f_{\text{pixel}}(W_{\text{core}}) = 1$. These clouds also experience high core volume fractions ($f_{\text{vol}} \sim 1$), as indicated by the scatter point sizes in Fig. 5. The other three permutations of $f_{\text{pixel}}(W_{\text{core}} \subseteq B_{\text{core}})$, $W_{\text{core}} \subseteq RH_{\text{core}}$, and $RH_{\text{core}} \subseteq B_{\text{core}}$ give an indication of cores sizes and of which cloud types show no overlap between different cores. As stated above, growing (dissipation) clouds show higher (lower) overlap between the different core types. The $W_{\text{core}} \subseteq W_{\text{core}}$ is almost twice as large as the $B_{\text{core}} \subseteq B_{\text{core}}$ and 30% - 40% larger than the $RH_{\text{core}} \subseteq RH_{\text{core}}$ along most of the growing branch. In conclusion, we see a strong tendency for the subset property of cores ($B_{\text{core}} \subseteq RH_{\text{core}} \subseteq W_{\text{core}}$) during the growth stages of clouds. This property ceases for dissipating and precipitating clouds, especially for the smaller clouds which show less overlap between core types.

To give an objective measure of the degree to which different core types can be used interchangeably, we define an interchangeable fraction (f_{int}), which is the multiplication of the two pixel fractions of a core pair (e.g. $f_{\text{pixel}}^{B \text{ in } RH} * f_{\text{pixel}}^{RH \text{ in } B}$). In Fig. 6 the f_{int} is shown for all clouds and the three core pairs. It can be seen that only a small percentage (<5%) of clouds can be considered to have fully interchangeable core types with $f_{\text{int}} > 0.75$. The RHcore, Wcore pair shows the highest degree of interchangeability (83%, 54% of clouds with $f_{\text{int}} > 0.25, 0.5$), showing high f_{int} for clouds at formation and growing stages, and sometimes also late dissipation. The Bcore, Wcore pair shows the lowest degree of interchangeability (46%, 6% of clouds with $f_{\text{int}} > 0.25, 0.5$), with mature growing clouds showing the highest f_{int} values. The Bcore, RHcore pair shows similar results, but with slightly higher f_{int} values on average.

5.3. Revisiting the core-shell model

Here we test how well the core-shell model can be applied to the 3 types of cores in different clouds seen in a warm cumulus cloud field. We test both the location of the cores with respect to the cloud center and horizontal profiles of the three types of core parameters within the cloud. In Fig. 7 the normalized distances (D_{norm}) between the total cloud centroid and each specific physical core centroid locations (i. e. $D_{norm, Centroid}$) are evaluated. Since clouds are not always axisymmetric, we also test the distances between total cloud COG and core COG ($D_{norm, COG}$) since the COG gives a better representation for where cloud and core mass are concentrated. We take $D_{norm} < 0.2$ as a threshold for cores located near the centroid or COG and $D_{norm} > 0.8$ as a threshold for cores located at the cloud edges. For all core types, the large majority of clouds' cores are centered near the clouds' centroid or COG. Only less than 1% of the clouds' cores reside at the cloud edges, mostly seen for small dissipating clouds. Distances between cloud COG and core COG yield smaller values than for distances between centroids, implying that the mass is not equally distributed within the clouds and hence the centroid may be "missing" the true cloud center in terms of mass distribution.

Along the growing branch the ~~cloud centroid clouds~~ and physical ~~cores' centroids~~ ~~cores~~ tend to be ~~of centered in~~ close proximity, while during cloud dissipation the ~~cores' centroids~~ ~~cores~~ tend to increase in distance from the cloud's center. This type of evolution is most prominent for the ~~W_{core} , W_{core}~~ , which shows a clear gradient of transition from small (dark colors) to large (bright colors) distances. ~~The B_{core}~~ Focusing on $D_{norm, COG} < 0.2$, the B_{core} shows a more complex transition, from intermediate distance values (~ 0.5) at cloud formation, lower chance to near zeros values along the mature part be in proximity of the growing branch, back to large values in the dissipation branch. Along the growing branch RH_{core} shows distances comparable to the W_{core} (except for large distances at cloud formation). However, compared to the cloud COG (76%) than the other two core types, RH_{core} shows the smallest distances to the geometrical core during cloud dissipation. (83%). This is manifested by a relative absence of bright colors for dissipating clouds in Fig. 6.

They may be due to a larger prevalence of cloud edge B_{core} pixels during dissipation can be explained by adiabatic heating due to weak downdrafts (see Sect. 4 here and Sect.

4.2, in Part II) which are expected at the cloud periphery. The fact that there is little overlap between B_{core} and both W_{core} and RH_{core} pixels in). Compared to the other clouds, the W_{core} shows a slightly larger probability of being located at the cloud edge in small dissipating clouds (see Fig. 5) serves to verify this assumption. The relative absence of isolated RH_{core} pixels at the cloud edges can be explained by the fact the pixels closest to the cloud's edge are most susceptible to mixing with non-cloudy air and evaporation, yielding subsaturation conditions. The innermost pixels are "protected" from such mixing and thus we can expect most RH_{core} pixels to be located near the geometrical core.

The W_{core} case is less intuitive. During. This can be due to the fact that during cloud dissipation complex patterns of updrafts and downdrafts within the cloud can create scenarios where the W_{core} centroid is located anywhere in the cloud. However, the results show that most small dissipating clouds tend to have their W_{core} pixels concentrated at the cloud edges. Comparing Fig. 6 with Figs. 4 and 5, we can see that these pixels comprise only a tiny fraction of the already small clouds and do not overlap with RH_{core} and B_{core} pixels and thus are not related to significant convection processes. Further analysis shows that the maximum updrafts in these clouds rarely exceed 0.5 m/s (i.e. 90% of clouds with normalized distance > 0.9 have a maximum updraft of less than 0.5 m/s), and can thus be considered with near neutral vertical velocity. W_{core} is comprised of very weak updrafts and located anywhere in the cloud.

Further analysis shows that most clouds with $D_{norm,COG} > 0.2$ values can be attributed to the relatively larger sized clouds which typically contain multiple cores within them (Fig. 8). For the B_{core} , RH_{core} , and W_{core} , 68%, 79%, and 81% of the cloud scatter analyzed (which contain a core) have a single core, respectively. Thus, most clouds have a single core. Moreover, it is more probable to find multiple buoyancy cores in a cloud than vertical velocity cores. This is surprising given our choice of "weak" W_{core} thresholds (i.e. positive values) and indicates that vertical velocity patterns are relatively well-behaved in cumulus clouds, at least for the LES scales chosen here. For clouds with a single core, growing branch cloud COG and core COG are co-located at the same point. A gradual transition to larger distances is seen as the clouds dissipate to lower mean LWP values. In total, above 80% of single core clouds have $D_{norm,COG} < 0.2$, for all core types. For clouds with multiple cores, about 50% of clouds show large

distances ($D_{norm,COG} > 0.2$), with little difference between growing branch and dissipating branch clouds. This is to be expected since a large cloud with multiple cores should have a COG somewhere between those cores, explaining the larger normalized distances.

The core-shell model assumes the highest values (of a core parameter in question) are located at the center of the cloud (Heus and Jonker, 2008). Is this indeed the case in clouds? In Fig. 9 we observe the likelihood and shape of pre-defined categories of horizontal profiles for core parameters. Profiles are taken along the horizontal plane of the cloud's COG, with distances normalized to cloud maximum horizontal size so that different cloud sizes can be averaged together. Only clouds with at least 3 pixels in the horizontal plane are taken. Profile categories include, i) core-shell (CS) profiles, which have a positive, maximum value near the COG at $D_{norm,COG} < 0.2$, ii) displaced core-shell profiles (DCS), which have a positive, maximum value somewhere between the COG and periphery at $0.2 < D_{norm,COG} < 0.8$, iii) periphery core (PC) profiles, which have a positive, maximum value at the cloud periphery at $D_{norm,COG} > 0.8$, and iv) no core (NC) profiles, which are comprised of only negative values. We take only clouds with a single core (or no core), since clouds with multiple cores show more complex profiles that represent a superposition of several single core profiles. The data is further divided to growing and dissipating stages of clouds by checking if a cloud grew in mass compared to the previous time step.

For all core types, there are more single core (and no core) growing clouds (~55-57%) than dissipating clouds. Generally, it can be seen that the CS category profile is the most prevalent in clouds with single cores, ranging from a maximum of 66% of growing cloud Wcore profiles to a minimum of 26% of dissipating cloud Bcore profiles. As seen in Figs. 4, 7, and 8, growing clouds show a relatively higher percentage of the CS and DCS categories, while dissipation clouds show relatively higher percentages of PC and NC category profiles. The Wcore and RHcore profiles show similar behavior, with decreasing prevalence from CS category to NC category (CS > DCS > PC > NC) category for growing clouds. For dissipating clouds, the partition is similar, but with PC category being the least prevalent (CS > DCS > NC > PC). The main difference in the partition to categories in Bcore profiles is the increasing prevalence and dominance of the NC category, as seen in previous analyses. For example, NC profiles are almost

non-existent in growing clouds for the Wcore and RHcore definitions ($\leq 1\%$), but second most prevalent using the Bcore definition (28%). Out of the three core types, the Wcore shows the highest probability for matching CS and PC categories, the RHcore for DCS category, and the Bcore for NC category.

On average, the CS category profiles show a monotonic decrease in value from positive to negative values. For growing clouds, vertical velocity may stay positive throughout the horizontal profile, not necessarily showing a downdraft “shell”. The DCS category profiles show positive values from the COG to more than half the cloud size (or the entire cloud size for growing cloud vertical velocity) and have a maximum at $D_{norm} \sim 0.2$, indicating that they are only marginally displaced from the cloud COG. This may indicate that most DCS profiles can actually be considered as CS profiles, but for clouds with significant asymmetry the core maximum seems to be displaced. Merging of CS and DCS categories comprises 70% - 90% of all clouds. For both CS and DCS categories, the transition from core to margin (i.e. positive to negative values) occurs at shorter D_{norm} for dissipating clouds. This transition D_{norm} value also decreases gradually moving from the Wcore to the RHcore and then to the Bcore, indicating smaller core sizes for the latter core types. The NC profiles show little variance with distance from the COG.

All core (and margin) types show decreasing values moving from growing to dissipating clouds. A decrease in values is also seen when comparing the maximum of the CS, DCS, and PC mean profiles, respectively. An exception is seen for the buoyancy PC category, which shows a slightly higher buoyancy peak value for dissipating clouds. Compared to the RHcore and Wcore PC category profiles which show positive values throughout the cloud (with little change), for smaller than average clouds, the Bcore PC category shows a transition from margin at the COG to core at the periphery, for larger than average clouds. This transition to positive buoyancy is even more pronounced (i.e. reaches higher values) for dissipating multi-core clouds (not shown here) that tend to be significantly larger. This may indicate that a non-convective process is at play in creating these Bcores at the cloud periphery (see Part II).

5.34. Consistency of the cloud partition to core types

The results for cloud fields are summarized in Fig. 710 that presents the evolution of core fractions of continuous cloud entities (CCEs, see Sect. 2.5 for details) from formation to dissipation. Only CCEs that undergo a complete life cycle are averaged here. These CCEs fulfill the following four conditions: i) form near the LCL, ii) live for at least 10 minutes, iii) reach maximum cloud mean LWP values above 10 g m^{-2} , and iv) terminate with mass value below 10 g m^{-2} . As a test of generality, we performed this analysis for Hawaiian and CASS warm cumulus cloud field simulations in addition to the BOMEX one. For each simulation, hundreds of CCEs are collected (see panel titles) and their core volume fractions are averaged according to their normalized lifetimes (τ).

Consistent results are seen for all three simulations. Clouds initiate with a $W_{\text{core}}/W_{\text{core}}$ fraction of ~ 1 , $RH_{\text{core}}/RH_{\text{core}}$ fraction of ~ 0.8 , and $B_{\text{core}}/B_{\text{core}}$ fraction of $\sim 0 - 0.15$. The former two core types' volume fraction decreases monotonically with lifetime, while the latter core type's volume fraction increases up to $0.15 - 0.35$ at $\tau \sim 0.253$, and then monotonically decreases for increasing τ . The continental (CASS) simulation consistently shows lower buoyancy volume fractions than the oceanic simulations. This can be attributed to lower RH in the CASS cloudy layer ($60\% - 80\%$) compared with the oceanic simulations ($85\% - 95\%$). The lower RH increases entrainment and reduces buoyancy. The fact that clouds end their life cycle with non-zero volume fractions may indicate that some of the CCE terminate not because of full dissipation but rather because of significant splitting or merging events.

Normalized distances (D_{norm}) between CCE core and cloud are also shown in Fig. 10 (middle column). Both distances between core centroid and (solid lines) and COG (dashed lines) to total cloud centroid (and COG are shown. As seen in Fig. 7, middle column) $D_{\text{norm},\text{COG}}$ shows smaller values, indicating that the COG better indicates the "true" cloud center compared with the centroid. Distances tend to monotonically increase for $RH_{\text{core}}/RH_{\text{core}}$ and $W_{\text{core}}/W_{\text{core}}$ with CCE lifetime for all simulations. The gradient of increase is larger at the later stages of CCE lifetime. Initially the $W_{\text{core}}/W_{\text{core}}$ is closer to the geometrical core but at later stages of CCE lifetime (typically $\tau > 0.58$) this switches and $RH_{\text{core}}/RH_{\text{core}}$ remains the closest. As seen above, for the first (second) half of CCE lifetime, the distance between $B_{\text{core}}/B_{\text{core}}$ centroid and cloud centroid $B_{\text{core}}/D_{\text{norm}}$ decreases (increases), starting at normalized distances

abovearound 0.42 for all simulations. The physical cores' COG stay closer to the geometrical corecloud COG ($D_{norm} < 0.52$) for the majority of their lifetimes for the three cases. However, the assumption that a cloud's core (by any definition) is also indicative of the cloud's centroid only applies to a fraction of that lifetime. Taking again the value $\frac{D_{norm}}{D_{norm,COG}} = 0.252$ as a threshold for physical cores centered near the cloud centroidCOG, Bomex, Hawaii, and CASS simulation CCEs' W_{core} Wcore all cross this threshold at $\tau = 0.8, 0.6, \text{ and } 0.65, \text{ respectively.}$ Thus, the core-shell geometrical model is mostly true for the first two thirdsabout 90% of a typical cloud's lifetime.

The analysis of core subset properties (Fig. 710, right column) shows that the assumption $B_{core} \subseteq RH_{core} \subseteq W_{core}$ Bcore \subseteq RHcore \subseteq Wcore is true for the initial formation stages of a cloud. Although the corresponding pixel fractions decrease slightly during the lifetime of the CCE, they remain above 0.9 (e.g. B_{core} Bcore is 90% contained within RH_{core} RHcore). A sharp decrease in pixel fractions is seen for $\tau > 0.8$ ($\tau > 0.5$ for the CASS simulation), as the overlaps between the different cores is reduced during dissipation stages of the cloud. For all simulations, the highest pixel fraction values are seen for the B_{core} Bcore inside W_{core} Wcore pair, followed by RH_{core} RHcore inside W_{core} Wcore pair, and B_{core} Bcore inside RH_{core} RHcore pair showing lower values. In addition, it can be seen that the variance of average pixel fraction (per τ) increases with increase in τ . This is due to the fact the all CCEs initiate with almost identical characteristics but may terminate in very different ways. In part II of this work we show that this variance is highly influenced from precipitation which contributes to more significant interactions between clouds (Heiblum et al., 2016b).

6. Summary

In this paper we study the partition of warm convective clouds to core and margin according to three different definitions: i) positive vertical velocity (W_{core} Wcore), ii) relative humidity supersaturation (RH_{core} RHcore), and iii) positive buoyancy (B_{core} Bcore), with emphasis on the differences between those definitions. Using theoretical considerations of both an adiabatic cloud column and a simple two parcel mixing model (see appendix A and B), we support our simulated results as we show

that the B_{core} is expected to be the smallest of the three. This finding is in line with previous works that showed that negative buoyancy is prevalent in cumulus clouds for a wide range of thermodynamic conditions (de Roode, 2008; Paluch, 1979; Taylor and Baker, 1991). This is due to the fact that entrainment into the core (i.e. mixing with non-cloudy environment or mixing with the margin regions of the cloud) may result in sub-saturation, followed by evaporation that always has a negative net effect on buoyancy. The same process has an opposing effect on the relative humidity of the mixed parcel and acts to reach saturation. Entrainment (or mixing) also acts to decrease vertical velocity, but at slower manner compared to the time scales of changes in the buoyancy and relative humidity. In addition, the supersaturation equation (Eq. (3)) predicts that it is unlikely to maintain supersaturation in a cloudy volume with negative vertical velocity. Hence, W_{core} can be expected to be the largest of the three cores.

Using numerical simulations of both a single cloud and cloud fields of warm cumulus clouds, we show that during most stages of clouds' lifetime, W_{core} is indeed the largest of the three and B_{core} the smallest. ~~In addition to~~ Only 2% of clouds are dominated (in volume fraction) by the differences in their sizes, the three cores tend to be subsets of one another (and located around the cloud geometrical center), in the following order: $B_{\text{core}} \subseteq RH_{\text{core}} \subseteq W_{\text{core}}$. This property is most valid for a cloud at its initial stages and breaks down gradually during a cloud's lifetime B_{core} , while 44%, 83% of clouds are RH_{core} , W_{core} dominated. The warm convective cloud fields simulated here typically have a transition layer near the lifting condensation level (LCL). Thus, the lower parts of the clouds are negatively buoyant or even lack a B_{core} at formation. After cloud formation internal growth processes (i.e. condensation and latent heat release) increase the B_{core} until dissipation processes become dominant and the B_{core} decreases quickly due to entrainment. In contrast, clouds are initially dominated by the W_{core} and RH_{core} (fractions close to 1). The fractions of these cores then decrease monotonically with cloud lifetime.

During dissipation stages, the clouds are mostly margin dominated, such that most of the small mass dissipation cloud fragments are entirely coreless. However, several small mass dissipating cloud fragments which shed off large cloud entities (with large

COG height) may be core dominated, especially when using the RH_{core} vertical velocity core definition. The same is observed for small precipitating cloud fragments which reside below the convective cloud base. We note that the results here are similar for both volume and mass core fractions out the cloud's totals, with the core mass fractions being larger due to a skewed distribution of cloud LWC which favors the core regions. Moreover, we show that these results are consistent for various levels of aerosol concentrations (will be seen in Part II) and different thermodynamic profiles used to initialize the models.

In addition to the differences in their sizes, the three cores tend to be subsets of one another, in the following order: $B_{core} \subset RH_{core} \subset W_{core}$. This property is most valid for a cloud at its initial stages and breaks down gradually during a cloud's lifetime. The decrease in overlap between different core types during dissipation implies that minor local effects enable core existence rather than cloud convection. Only during growth and mature stages can the three core definitions be used interchangeably with least amount of difference in core sizes. Generally, the RH_{core} , W_{core} pair are most interchangeable, while the B_{core} , W_{core} pair the least.

With respect to cloud morphology, ~~it is shown that during cloud growth, which comprises the majority of a warm cloud lifetime, the physical cores are centered clouds are composed from single cores (for all core types), located near the cloud's geometrical core, as is intuitively expected from a cloud's core. This matches the convective cloud centroid/COG, and fit the intuitive core-shell model. An exception to this is the initial of decreasing core parameter values from cloud center to periphery. This is especially true during cloud growth stages, where the B_{core} centroid can be located far from the cloud's centroid. During dissipation (i.e. approximately the last third of a cloud's lifetime), the core shell model no longer applies to the clouds, as, as during dissipation the cores may decouple from the geometrical core and often comprise just a few isolated pixels at the cloud's edges. The W_{core} and B_{core} pixels tend to be more peripheral than RH_{core} during dissipation (see Sect. 5.2). Downdraft induced adiabatic heating at the clouds' edge (see more in Part II) promote positive buoyancy while decreasing the chance for supersaturation. During dissipation the overlap between different core types also decreases rapidly, implying that minor local effects enable core existence rather than cloud convection. Thus, only during mature growth stages can all three cores types~~

can be considered interchangeable. In terms of cloud lifetime, the core-shell model applies to at least 80% of a typical cumulus cloud lifetime. We note that using the COG as a measure for the cloud and core geometrical centers yields smaller cloud to core distances than their centroids. Thus, the COG better represents the cloud physical center. Out of the three core types, the Wcore (Bcore) shows the highest (lowest) chance to be a single core in the cloud. This is despite choosing a low Wcore threshold of $W > 0$. Relatively large clouds tend to have multiple cores so that the mean (mass weighted) core COG location is displaced from the cloud COG. The Bcore COG shows the highest chance to be located away from the cloud COG. In some cases of larger clouds, the buoyancy horizontal profile may look exactly opposite to the core-shell one (i.e. maximum at periphery, minimum at center). This may be due to downdraft induced heating at the clouds' edge that promotes positive buoyancy (see more in Part II). In Part II of this work we use the insights gained here to understand aerosol effects on warm convective clouds, as are reflected by a cloud's partition to its core and margin.

Author Contributions

RH formulated the theoretical arguments, ran cloud field simulations and conducted the analyses, and wrote the final draft of paper. LP participated in writing the first draft, and performed single cloud simulations and relevant analyses. OA, GD, and IK participated in paper editing and discussions.

Appendix A: Buoyancy changes due to mixing of cloudy and non-cloudy parcels

Here we present a simple model for entrainment mixing between a cloudy parcel (either part of B_{core} or B_{margin}) and a dry environmental parcel. Entrainment

mixes the momentum, heat, and humidity of the two parcels. We consider the mixing of a unit mass of cloud parcel which is defined by two criteria:

$$\begin{aligned} S_1 &\geq 1 \\ B_1 &> 0 \text{ or } B_1 < 0 \end{aligned}$$

with a unit mass of dry environment parcel, defined by:

$$S_2 < 1$$

and explore the properties of the resulting mixed parcel.

Assume that T_1, T_2, T_3 are the initial temperatures of the cloudy, environmental, and resulting mixed parcel, respectively. $q_{v1}, q_{v2}, q_{v3}, \theta_1, \theta_2, \theta_3$, and q_{l1}, q_{l2}, q_{l3} are their respective vapor mixing ratios, potential temperatures, and liquid water contents (LWC).

The change in buoyancy due to mixing will be:

$$dB_{mix} = g * \left(\frac{\theta_3 - \theta_1}{\theta_2} + 0.61(q_{v3} - q_{v1}) - (q_{l3} - q_{l1}) \right) \quad (\text{A1}),$$

with

$$T_3 = \mu_1 \cdot T_1 + \mu_2 \cdot T_2 \quad (\text{A2}),$$

$$q_{v3} = \mu_1 \cdot q_{v1} + \mu_2 \cdot q_{v2} \quad (\text{A3}),$$

$$q_{l3} = \mu_1 \cdot q_{l1} + \mu_2 \cdot q_{l2} \quad (\text{A4}),$$

where μ_1 and μ_2 are the corresponding mixing fractions. We assume that the mixed parcel is at the same height as the cloudy and environmental parcels, and that the mean environmental temperature at that height stays the same after mixing. The potential temperature (θ) is calculated using its definition.

After the mixing process, the resultant mixed parcel may be subsaturated ($S_3 < 1$), and cloud droplets start to evaporate. The evaporation process increases the humidity of the parcel. ((Korolev et al., 2016), Eq. (A8)) calculated the amount of the required liquid water for evaporation, in order to reach $S=1$ again:

$$\delta q = \frac{C_p R_v T_2^2}{L^2} \ln \left(\frac{1 + \frac{e_s(T_3) R_a L^2}{P C_p R_v^2 T_3^2}}{1 + S_3 \frac{e_s(T_3) R_a L^2}{P C_p R_v^2 T_3^2}} \right) \quad (\text{A5}),$$

Where C_p is a specific heat at constant pressure, $e_s(T_3)$ is the saturated vapor pressure for the mixed temperature, P is pressure, L is latent heat, R_v, R_a are individual gas constants for water vapor and dry air, respectively. If the mixed parcel contains sufficient LWC to evaporate δq amount of water, the mixed parcel will reach saturation. We note that Eq. (A5) holds for cases where $|T_1 - T_2| < 10^\circ C$, which is well within the range seen in our simulations of warm clouds.

Assuming the average environmental temperature stays the same after evaporation, the buoyancy after evaporation is calculated using the following formulas:

$$dB_{evap} = g \cdot \left(\frac{d\theta'_{evap}}{\theta_2} + 0.61 dq_{v_{evap}} - dq_{l_{evap}} \right) \quad (\text{A6}),$$

$$d\theta'_{evap} = dT_{evap} \quad (\text{A7}),$$

From the first law of thermodynamics:

$$C_p \cdot dT_{evap} = -L \cdot dq_{v_{evap}} \quad (\text{A8}).$$

The water vapor is the amount of liquid water lost by evaporation:

$$dq_{v_{evap}} = -dq_{l_{evap}} = \delta q \quad (\text{A9}),$$

From the above we get:

$$dB_{evap} = g \cdot \delta q \left(1.61 - \frac{L}{c_p \theta_2} \right) \quad (\text{A10}).$$

For a wide temperature range between $200 < \theta_2 < 300[K]$, dB_{evap} is always negative. This result is not trivial because evaporation both decreases the T and increases the q_v which have opposite effects. The total change in buoyancy is taken as the sum of dB_{evap} and dB_{mix} .

Figure A1 presents a phase space of possible changes in cloudy pixel buoyancy due to mixing with outside air, for various thermodynamic conditions, and a mixing fraction of 0.5. The initial cloudy parcel is chosen to be saturated ($S=1$) and includes a LWC of

1 g kg⁻¹. The pressure is assumed to be 850 mb, and the temperature 15°C. However, we note that the conclusions here apply to all atmospherically relevant values of pressure, temperature, supersaturation (values of RH>100%), and LWC in warm clouds. The X-axis in Fig. A1 spans a range of non-cloudy environment relative humidity values (60% < RH < 100%), and the Y-axis spans a temperature difference range between the cloud and the environment parcels ($-3^\circ < dT < 3^\circ$). The initial (B_i) and final (B_f , after entrainment) buoyancy values, and the differences between them can be either positive or negative. The regions of $B_i > 0$ ($B_i < 0$) in fact illustrate the effects of entrainment on ~~B_{core} (B_{margin})~~ B_{core} (B_{margin}) parcels.

Appendix B: Buoyancy changes due to mixing of core and margin parcels

Following the notations of appendix A, we now consider the mixing of two cloudy parcels, one part of ~~B_{core}~~ B_{core} and one part of ~~B_{margin}~~ B_{margin} . For simplicity, we choose the case where both parcels are saturated and have the same LWC of 0.5 g kg⁻¹:

$$\begin{aligned} S_{core} &= S_{margin} = S_{cloud} = 1 \\ q_{l_{core}} &= q_{l_{margin}} = q_{l_{cloud}} = 0.5 \end{aligned} \quad (B1).$$

The buoyancy of each cloudy parcel is determined in reference to the environmental temperature and humidity, T_{env} , $q_{v_{env}}$, so that:

$$B_{cloud} = g * \left(\frac{\theta_{cloud} - \theta_{env}}{\theta_{env}} + 0.61(q_{v_{cloud}} - q_{v_{env}}) - q_{l_{cloud}} \right) \quad (B2).$$

As mentioned in the main text, we take a temperature range of $T_{env} - 3^\circ c < T_{cloud} < T_{env} + 3^\circ c$. Each cloudy parcel's temperature also dictates its saturation vapor pressure $e_s(T_{cloud})$ and therefore also its humidity content, $q_{v_{cloud}}$. Plugging these into Eq. (B2), one can associate each temperature/humidity pair with the ~~B_{core} or B_{margin}~~ B_{core} or B_{margin} :

$$\begin{aligned} T_{core} &= T_{cloud}(B_{cloud} > 0), q_{v_{core}} = q_{v_{cloud}}(B_{cloud} > 0) \\ T_{margin} &= T_{cloud}(B_{cloud} < 0), q_{v_{margin}} = q_{v_{cloud}}(B_{cloud} < 0) \end{aligned} \quad (B3).$$

The core and margin parcels can then be mixed (see appendix A) yielding a mixed parcel temperature and humidity content, and thus a new relative humidity. The buoyancy of the mixed parcel is obtained by inserting these parameters in Eq. (B2).

In Fig. B1 the resultant buoyancy values and RH values after the mixing of B_{core} parcels with B_{margin} parcels are shown. As defined in Appendix A, temperature differences between the parcels and the environment are confined to $\pm 3^\circ\text{C}$. The reference environmental temperature, pressure, and RH are taken to be 15°C , 850 mb, and 90%, respectively. We note the main differences between this section and Appendix A are the absence of evaporation and the fact that the core and margin thermodynamic variables are the ones that vary while the reference environmental ones are kept constant.

It can be seen that all negatively buoyant parcels are colder than the environment and nearly all positively buoyant parcels are warmer than the environment, except for a small fraction that are slightly colder but positively buoyant due to the increased humidity. The transition from $B_f > 0$ to $B_f < 0$ near the 1 to 1 line indicates that B_f is approximately linearly dependent on the temperature differences with respect to the environment. In other words, if $|T_{core} - T_{env}| > |T_{margin} - T_{env}|$, the mixed parcel is expected to be part of the B_{core} (i.e. $B_f > 0$). The exponential increase in saturation vapor pressure with temperature is demonstrated by the results of the mixed parcel final RH, which all show supersaturation values. Additional sensitivity tests were performed for this analysis, showing only weak dependencies on environmental parameter values, while maintaining the main conclusions.

Figures

Figure 1. A schematic representation of a cloud field Center-of-gravity height (Y-Axis) vs. Mass (X-Axis) phase space (CvM in short). The majority of clouds are confined to the region between the adiabatic approximation (curved dashed line) and the inversion layer base height (horizontal dashed line). The yellow, magenta, red, and grey shaded regions represent cloud growth, gradual dissipation, cloud fragments which shed off large clouds, and cloud fragments which shed off precipitating clouds, respectively. The black arrows represent continuous trajectories of cloud growth and dissipation. The hatched arrows represent two possible discontinuous trajectories of cloud dissipation where clouds shed segments.

Figure 2. Four vertical cross-sections (at $t=8, 20, 30, 40$ minutes) during the single cloud simulation. Y-axis represents height [m] and X-axis represents the distance from the axis [m]. The black, magenta, green and yellow lines represent the cloud, W_{core} , RH_{core} and B_{core} , respectively. The black arrows represent the wind, the background represents the condensation (red) and evaporation rate (blue) [$\text{g kg}^{-1} \text{s}^{-1}$], and the black asterisks indicate the vertical location of the cloud centroid. Note that in some cases the lines indicating core boundaries overlap (mainly seen for RH and W cores).

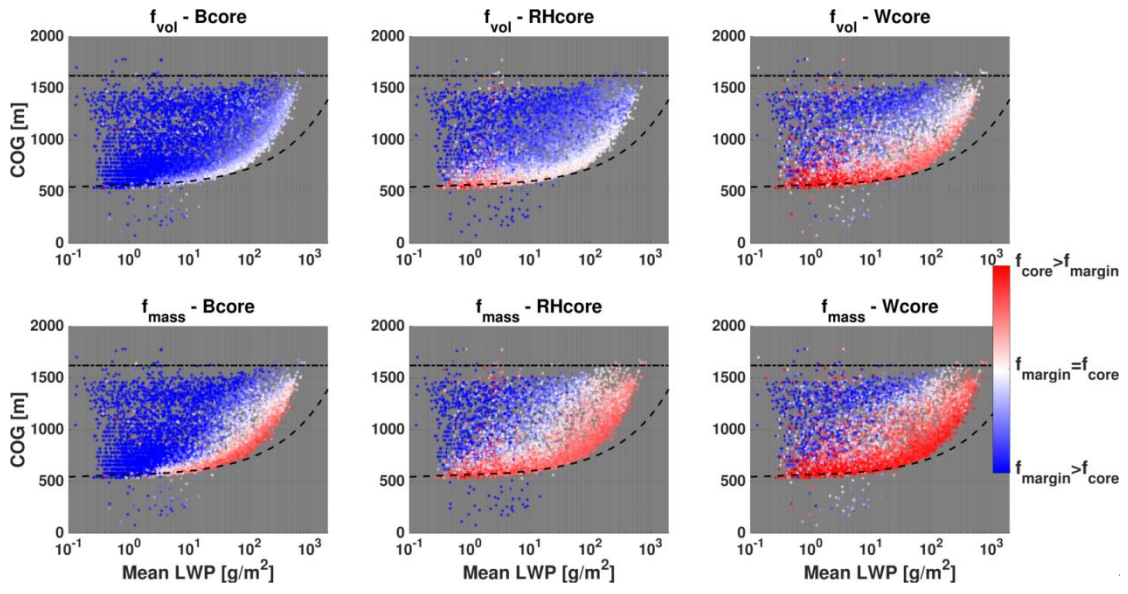

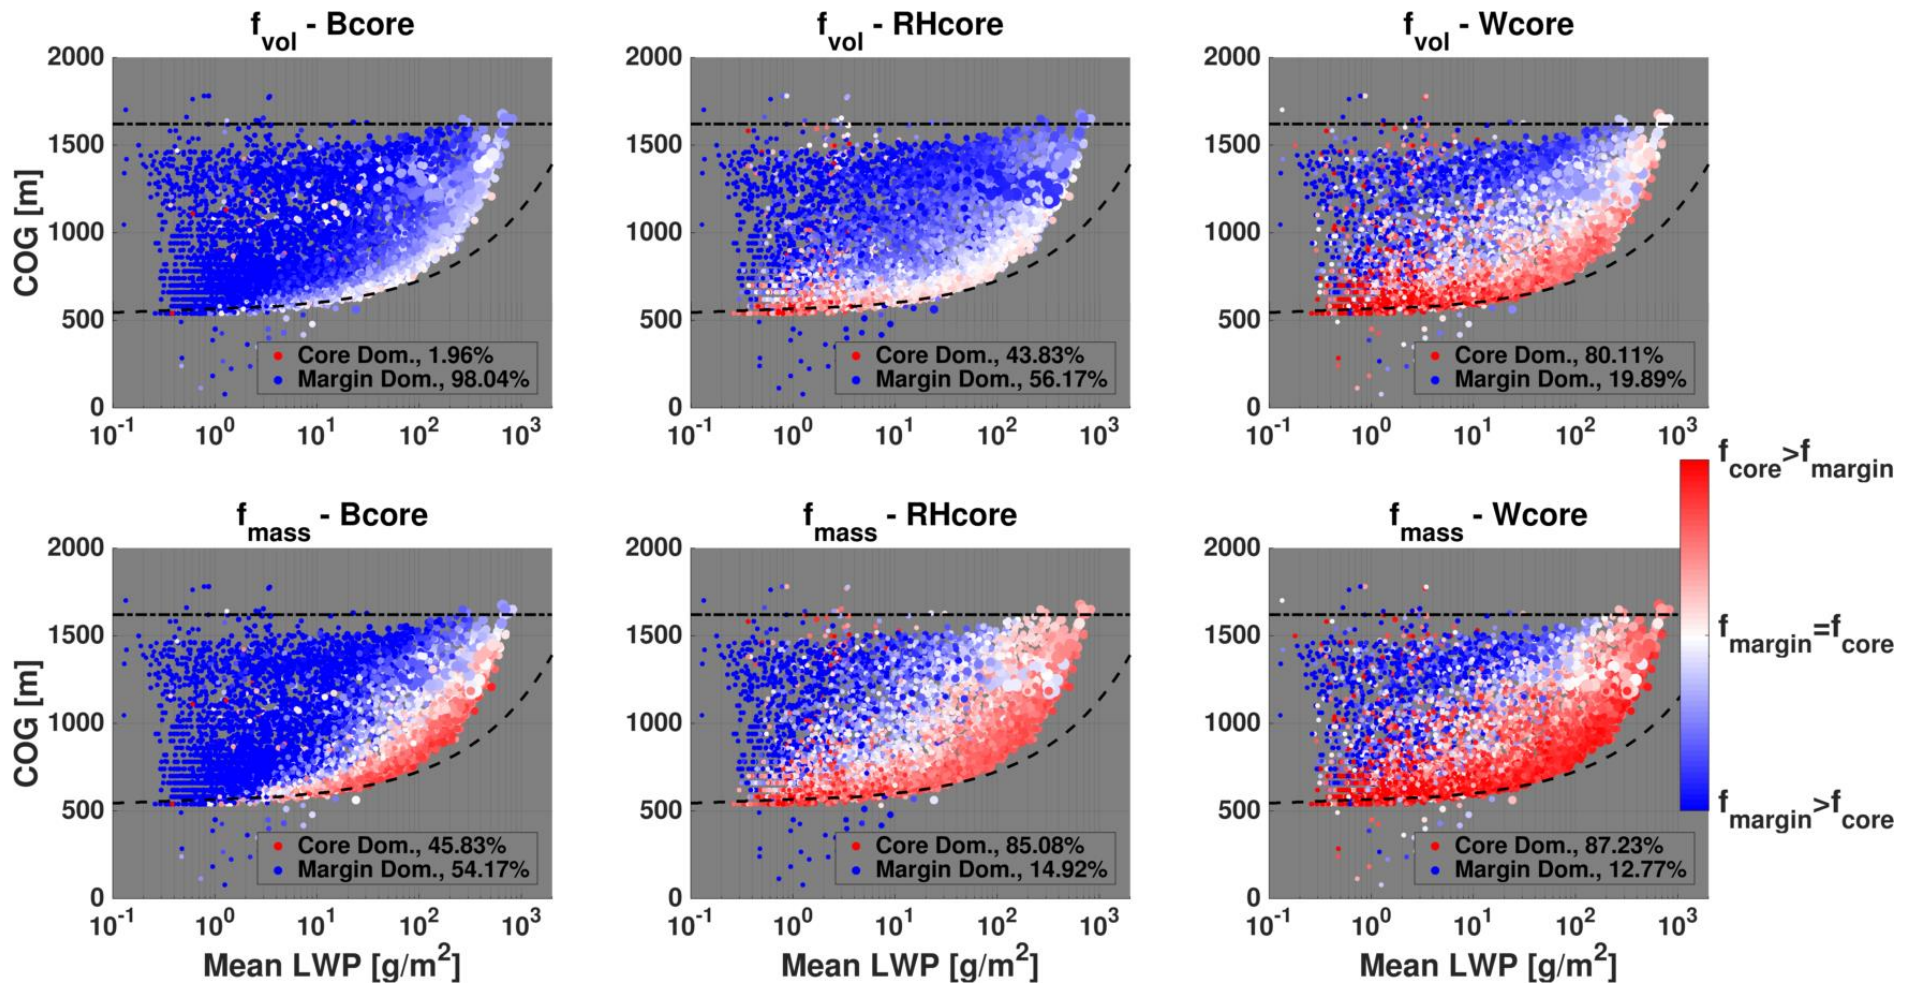

Figure 3. Temporal evolution of selected core properties, including: (a) The fraction of the cores' mass from the total cloud mass (f_{mass}), (b) the fraction of the cores' volume from the total cloud volume (f_{vol}), (c) the normalized distance between cloud centroid and core centroid (D_{norm}), and (d) the fraction of cores' pixels contained within another core (f_{pixel}), including all six permutations. See panel legends for descriptions of line colors.

1 Figure 4. CvM phase space diagrams of B_{core} (left column), RH_{core} (middle column), and W_{core} (right column) fractions for all clouds between
 2 3 h and 8 h in the BOMEX simulation. Both volume fractions (f_{vol} , upper panels) and mass fractions (f_{mass} lower panels) are shown. The red

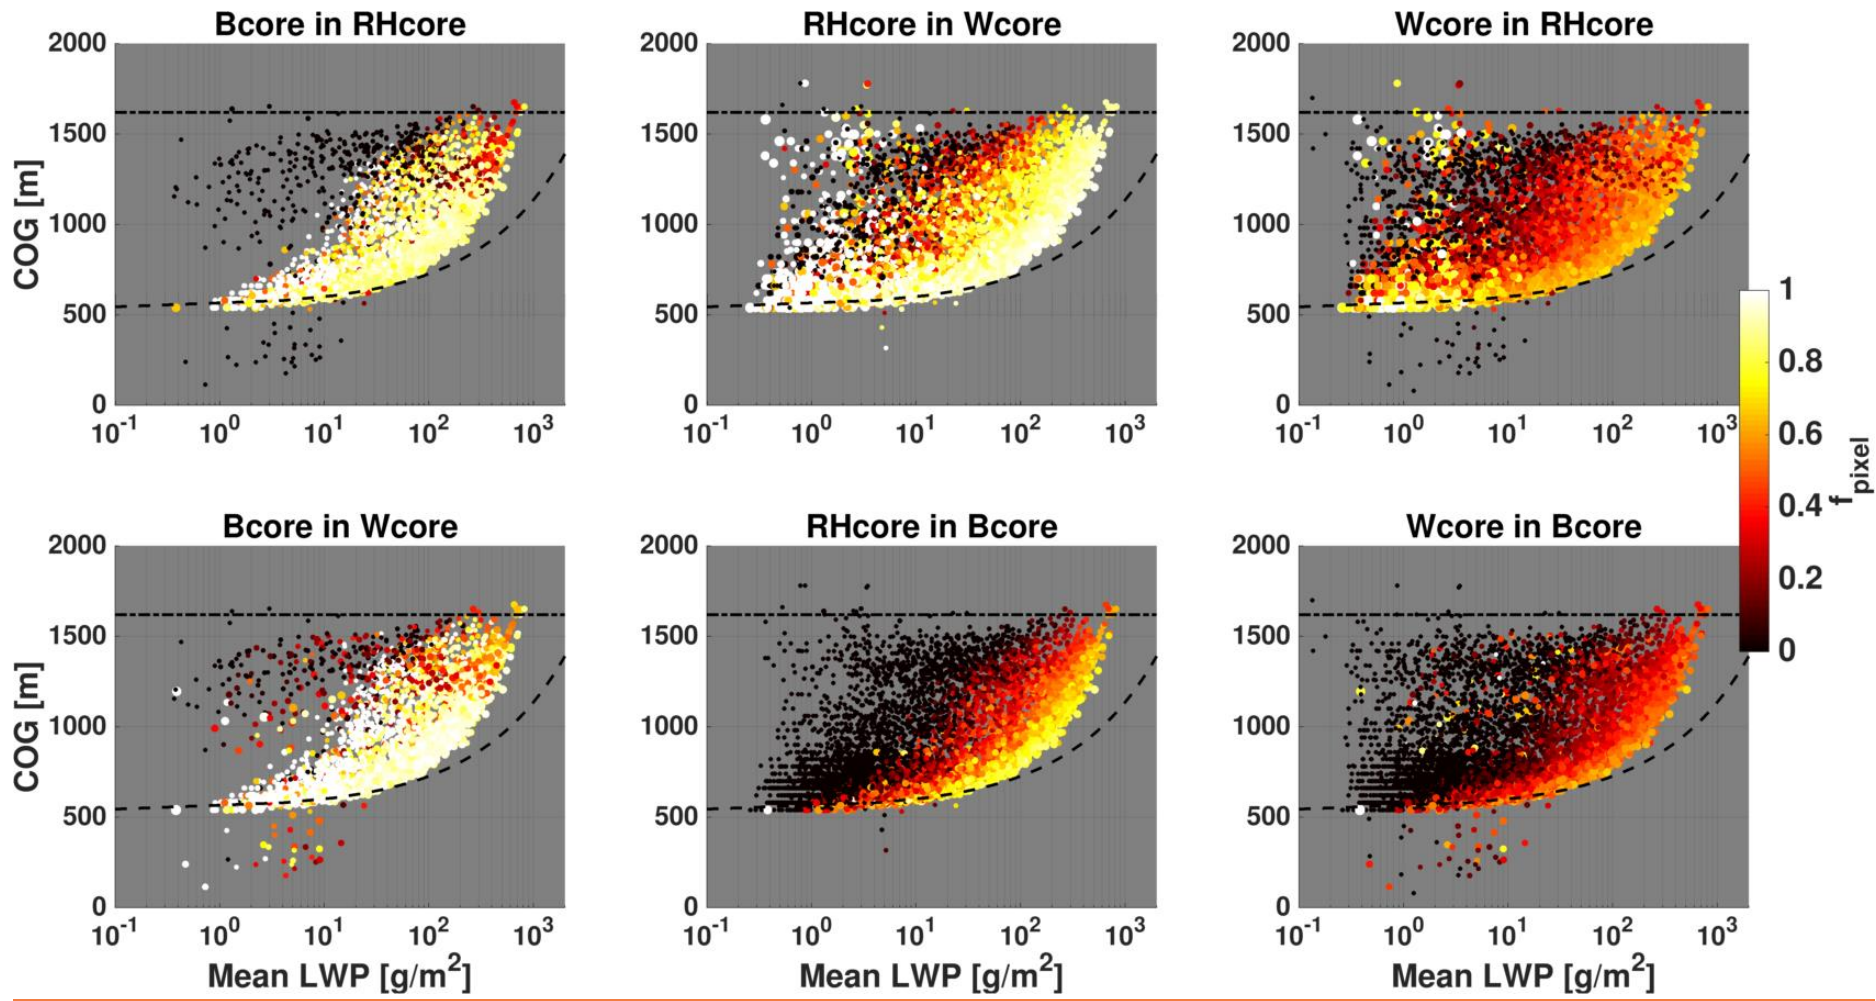

3 (blue) colors indicate a core fraction above (below) 0.5. The size of each point in the scatter is proportional to the cloud mean area, where the
4 smallest (largest) point corresponds to an area of 0.01 (2.36) km². The percentage of clouds that are core dominated ($f_{\text{vol}}, f_{\text{mass}} > 0.5$) is included
5 in panel legends. For a general description of CvM space characteristics the reader is referred to Sect. 2.4.

6

7

8

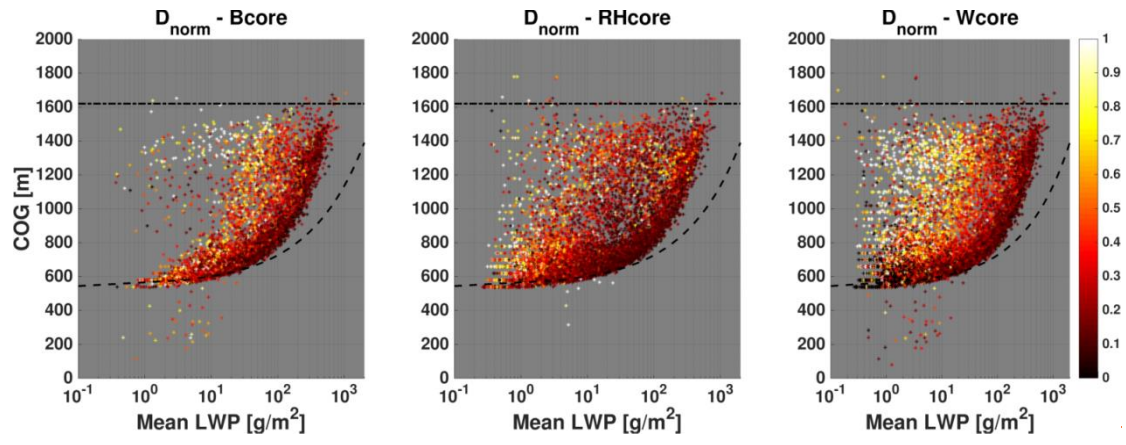

9

10 Figure 5. CvM phase space diagrams of pixel fractions (f_{pixel}) of each of the three cores within another core, including six different permutations
11 (as indicated in the panel titles). Bright colors indicate high pixel fractions (large overlap between two core types) while dark colors indicate low
12 pixel fraction (little overlap between two core types). *The differences in the scatter density and location for different panels are due to the fact that*
13 *only* Only clouds ~~which contain with a non-zero~~ core fraction ~~above zero~~ (for the core in question) are considered. ~~For example, (e.g. for the~~
14 ~~BuoyBcore~~ in ~~RHRHcore~~ panel (upper left), only ~~cloud~~ clouds that contain ~~some pixels~~ at least one pixel with positive buoyancy are considered).
15 Scatter point size is proportional to the minimum f_{vol} of the core pairs in question.

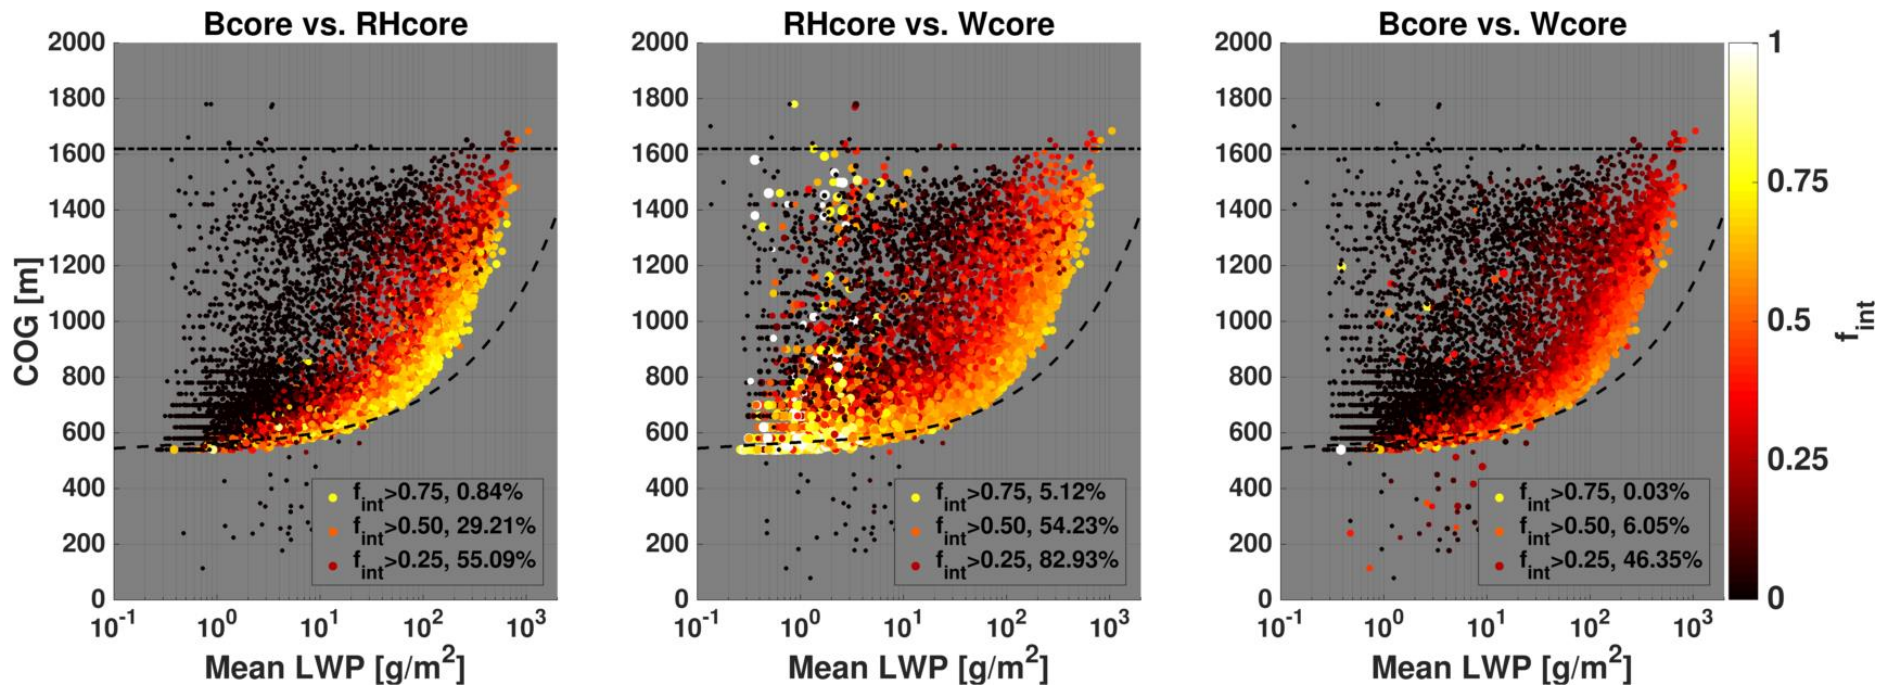

16

17

18

19

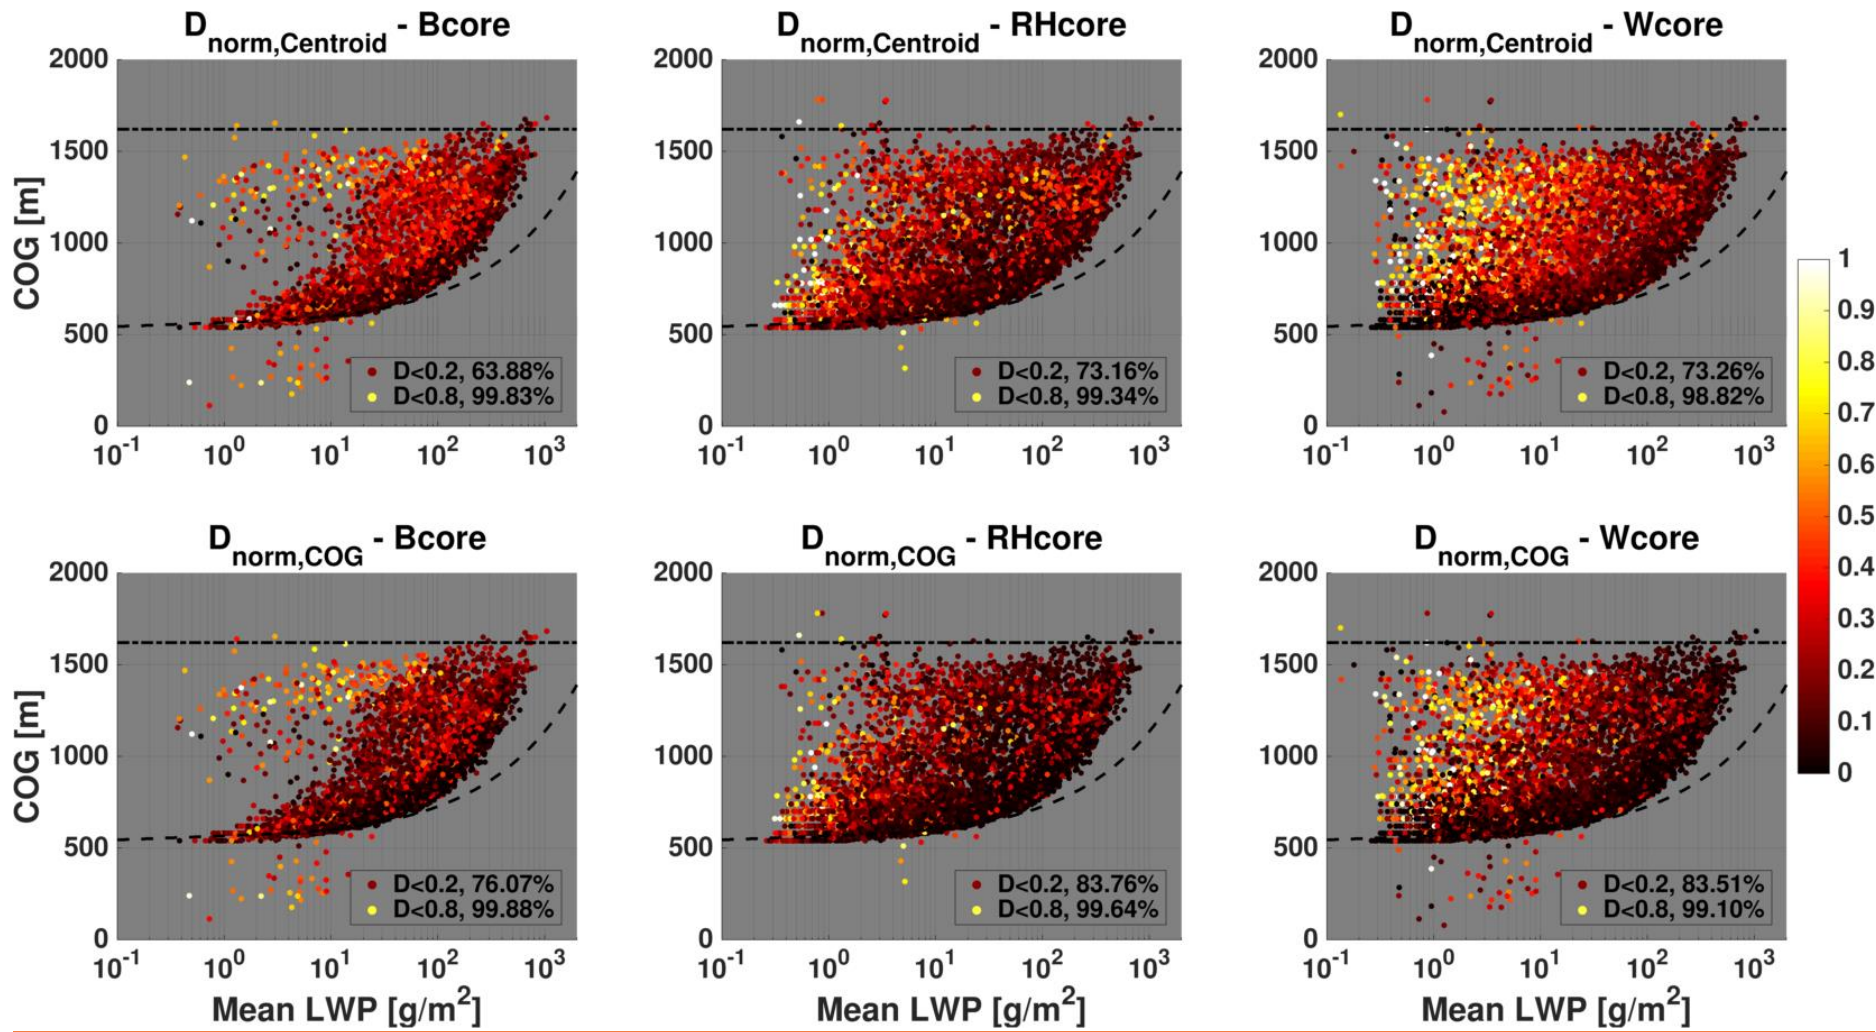

20

21 *Figure 6. CvM phase space diagrams of degree of interchangeability (f_{int}) for each of the core pairs (as indicated in the panel titles). Bright colors indicate*
 22 *high values (cores can be interchanged with little affect) while dark colors indicate small values (no overlap between cores). Only clouds with a core by at*
 23 *least one definition are considered. Scatter point size is proportional to the minimum f_{vol} of the core pairs in question. Panel legends include percentage of*
 24 *points (out of the scatter) with f_{int} above a certain threshold.*

25

26

27

28 Figure 7. CvM phase space diagrams of distances between core centroid ~~location~~ and cloud centroid ($D_{norm,centroid}$, top panels), and distances between
29 core COG and cloud COG ($D_{norm,COG}$, bottom panels) location, for the three different physical core types. The distances are normalized by the ~~cloud volume~~
30 radius (approximately the largest maximum distance possible) between the cloud centroid/COG and the cloud perimeter. Bright (dark) colors indicates
31 large (small) distances. Legends include percentage of points (out of the scatter) with D_{norm} below a certain threshold. As seen in Fig. 5, only clouds which
32 contain a core fraction above zero (for the core in question) are considered.

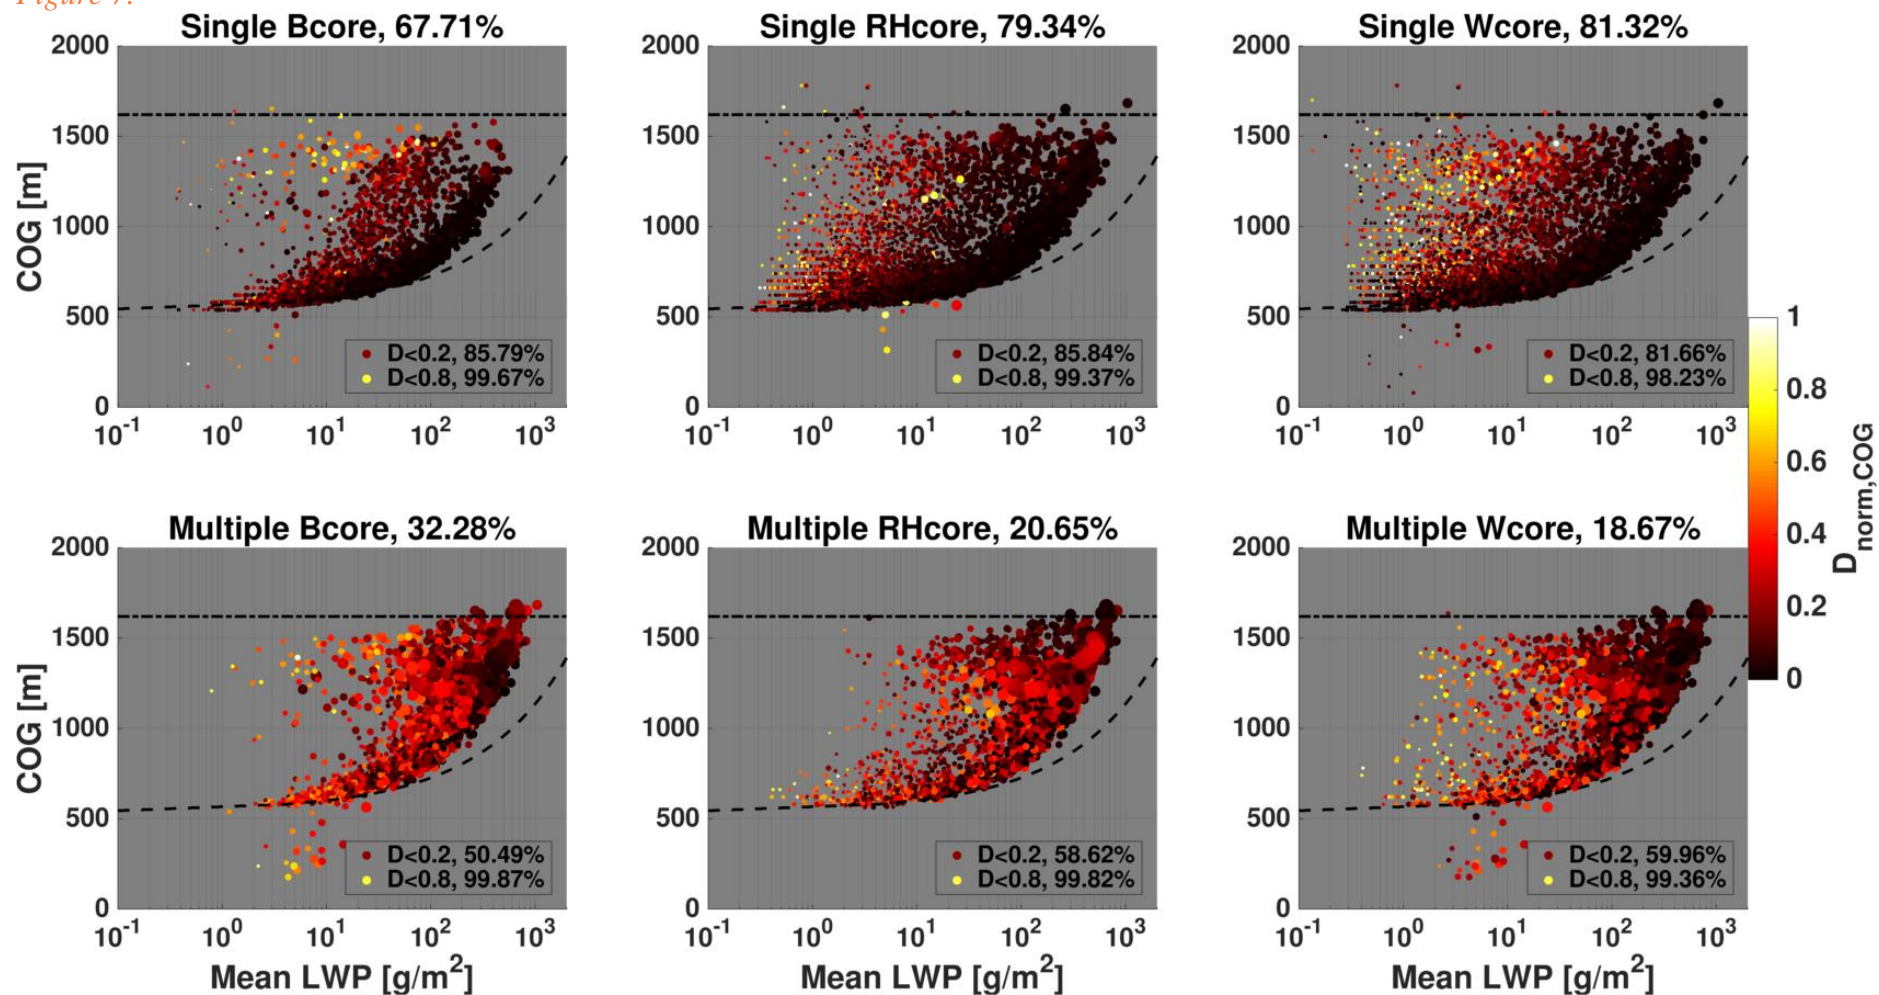

33

34

37

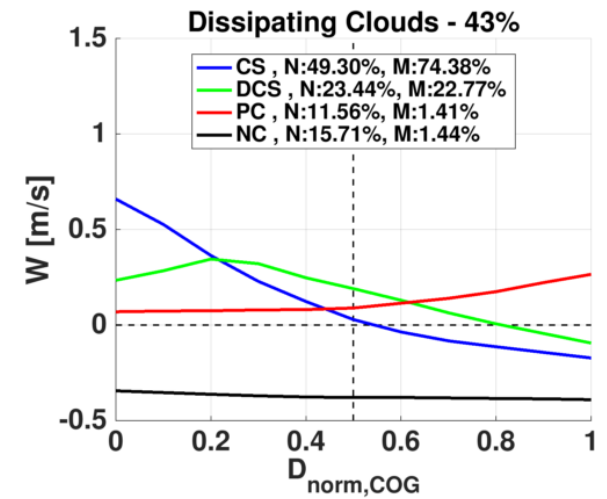

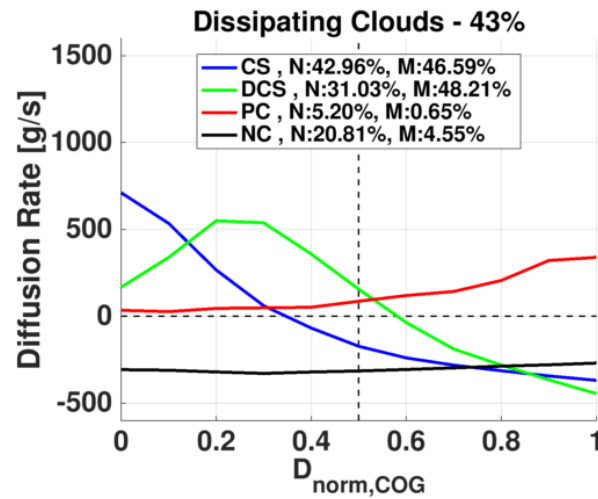

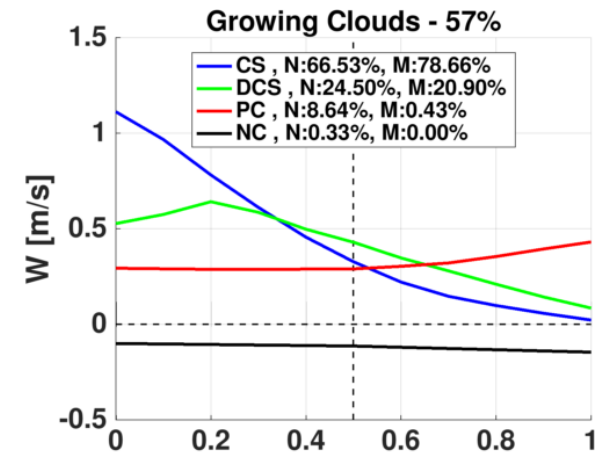

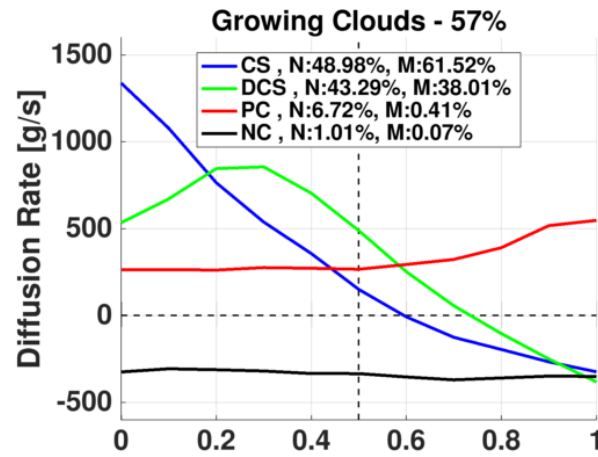

Figure 7.

38

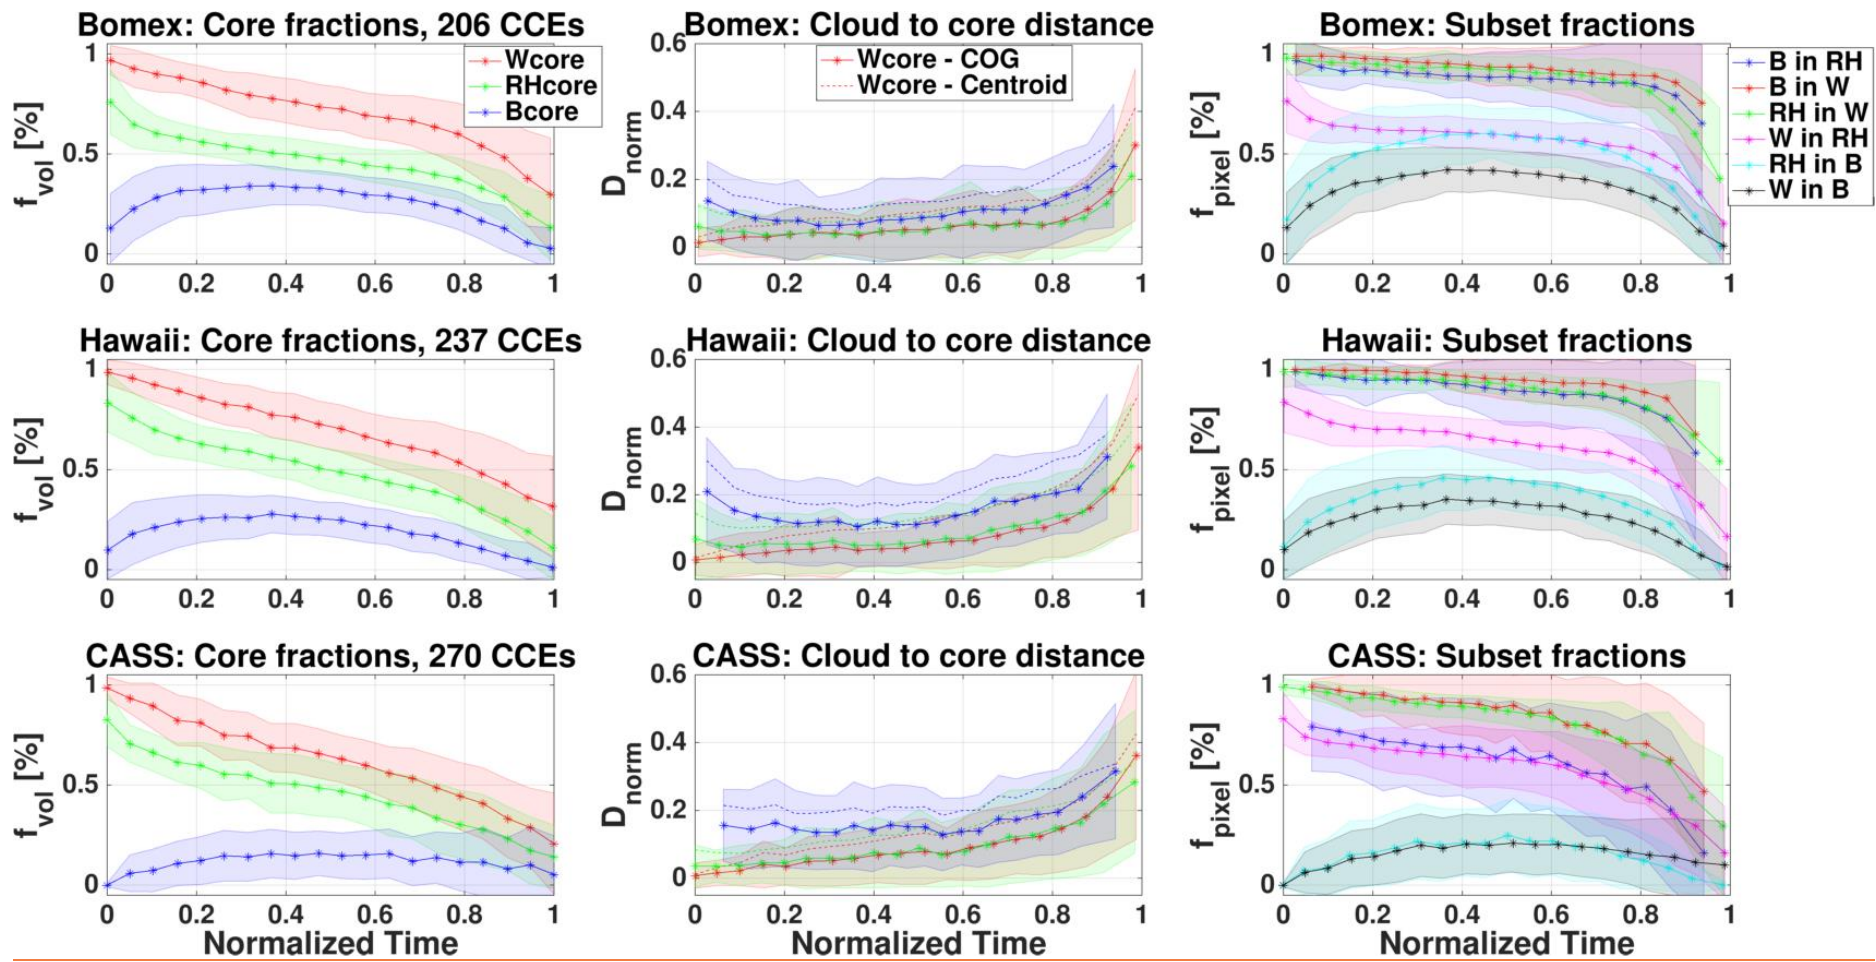

39 Figure 8. Same as Fig. 7, but for only distances between core COG and cloud COG ($D_{norm,COG}$). Scatter data is partitioned to clouds with a single core (top
40 panels) and multiple cores (top panels). The size of each point in the scatter is proportional to the cloud mean area.

41

43 Figure 9. Mean horizontal profiles of core parameters from the cloud COG to cloud edge, for clouds with single cores and no cores. Data is divided to growing
44 clouds (top) and dissipating clouds (bottom), where the horizontal distances are normalized by the maximum distance to cloud edge. Parameters include
45 buoyancy (left), diffusion rate (middle, taken as a proxy for the supersaturation core), and vertical velocity (right). The data is divided to profiles that match
46 core-shell (CS), displaced core-shell (DCS), peripheral core (PC), or no core (NC) categories, as indicated by the different line colors. The percentage of cloud
47 number (N) and cloud mass (M) attributed to each category are shown in the panel legends. We note that comparing the number percentages with mass
48 percentages for each category gives an indication for the relative sizes of the clouds (e.g. higher N% than M% indicates smaller clouds).

49

50

51 *Figure 10.* Normalized time series of CCE averaged core fractions for the BOMEX (upper row), Hawaii (middle row), and CASS (bottom row) simulations. Both
 52 core volume fractions (f_{vol} , left column), normalized distances between cloud and core ~~centroid locations~~ (D_{norm} , middle column), and pixel fractions of one
 53 core within another (f_{pixel} , right column) are considered. Normalized distanced between both COG locations (solid lines) and centroid locations (dotted lines)

54 *are shown.* Line colors indicated different core types (see legends), while corresponding shaded color regions indicate the standard deviation. Normalized
55 time enables to average together CCEs with different lifetimes, from formation to dissipation. The number of CCEs averaged together for each simulation is
56 included in the left column panel titles.

Figure A1. Phase space presenting the effects of entrainment on cloud buoyancy, where the initial cloudy parcel buoyancy (B_i) and final mixed parcel buoyancy (B_f) are considered. A mixing fraction of 0.5 is chosen. The initial cloudy parcel is saturated ($S=1$), has a temperature of 15°C , pressure of 850 mb, and LWC of 1 g kg^{-1} . The X-axis spans a range of environment relative humidity values (RH_{env}), and the Y-axis a temperature difference ($dT_{env}=T_{env}-T_{cld}$) range between the cloud and the environment parcels. Red color represents $B_i < 0$ & $B_f < 0$ (i.e. parcel stays negatively buoyant after the mixing), magenta represents $B_i < 0$ & $B_f > 0$ (i.e. transition from negative to positive buoyancy), green represents $B_i > 0$ & $B_f < 0$ (i.e. transition from positive to negative buoyancy), and blue represents $B_i > 0$ & $B_f > 0$ (i.e. parcel stays positively buoyant). The grey color represents mixed parcels that were depleted from water (LWC value lower than 0.01 g kg^{-1}) after evaporation, and are considered non-cloudy. The white line separates between areas where $B_f > B_i$ and $B_f < B_i$.

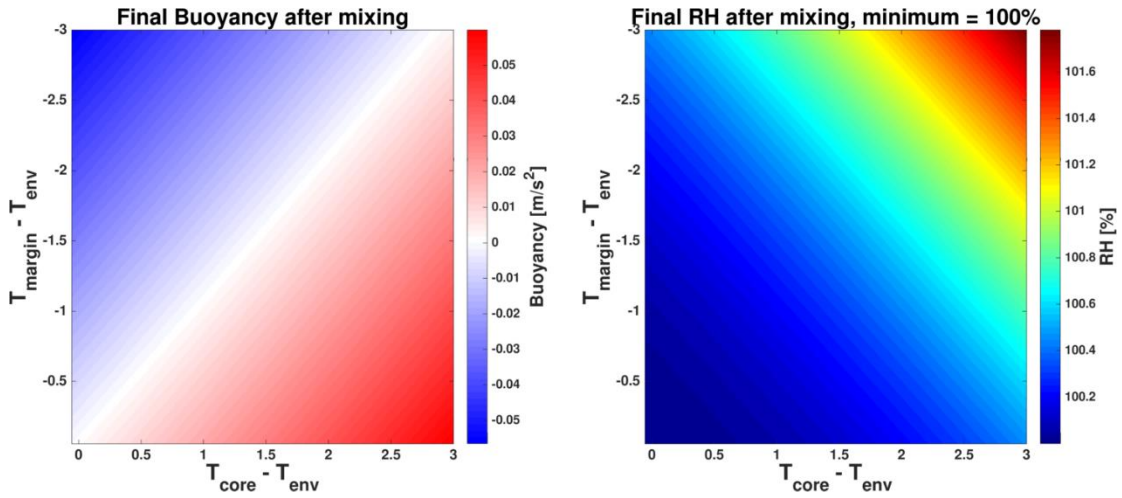

Figure B1. Phase space presenting the resultant buoyancy (left panel) and relative humidity (RH, right panel) when mixing B_{core} and B_{margin} parcels with equal RH but different temperatures. A mixing fraction of 0.5 is chosen. Both parcels are initially saturated ($RH=100\%$), and have a LWC of 0.5 g kg^{-1} . The environment has a temperature of 15°C and pressure of 850 mb . The X(Y)-axis spans the range of temperature differences between the B_{core} (B_{margin}) parcel and the environment.
