Abstract: Sentinel-2 is a very new programme of the European Space Agency (ESA) that is designed for fine spatial resolution global monitoring. Sentinel-2 images provide four 10 m bands and six 20 m bands. To provide more explicit spatial information, this paper aims to downscale the six 20 m bands to 10 m spatial resolution using the four directly observed 10 m bands. The outcome of this fusion task is the production of 10 Sentinel-2 bands with 10 m spatial resolution. This new fusion problem involves four fine spatial resolution bands, which is different to, and more complex than, the common pan-sharpening fusion problem which involves only one fine band. To address this, we extend the existing two main families of image fusion approaches (i.e., component substitution, CS, and multiresolution analysis, MRA) with two different schemes, a band synthesis scheme and a band selection scheme. Moreover, the recently developed area-to-point regression kriging (ATPRK) approach was also developed and applied for the Sentinel-2 fusion task. Using two Sentinel-2 datasets released online, the three types of approaches (eight CS and MRA-based approaches, and ATPRK) were compared comprehensively in terms of their accuracies to provide recommendations for

the task of fusion of Sentinel-2 images. The downscaled ten-band 10 m Sentinel-2 datasets represent important and promising products for a wide range of applications in remote sensing. They also have potential for blending with the upcoming Sentinel-3 data for fine spatio-temporal resolution monitoring at the global scale.

Keywords: Sentinel-2, image fusion, downscaling, area-to-point regression kriging (ATPRK)

1. Introduction

Sentinel-2 is a wide-swath and fine spatial resolution satellite imaging mission of the European Space Agency (ESA) developed in the framework of the European Union Copernicus programme (Drusch et al., 2012; Hagolle et al., 2015; Segl et al., 2015). According to the primary objectives of the programme, the Sentinel-2 mission is designed for data continuity and enhancement of the Landsat and SPOT missions. The Sentinel-2 satellite covers areas from -56° to 84° latitude, and the data are mainly intended to support global land services, including the monitoring of vegetation, soil and water cover, inland waterways and coastal areas. The Sentinel-2A satellite was launched on 23 June 2015 and is now in operation routinely. The addition of the complementary Sentinel-2B satellite will be launched in mid-2016. The twin satellites will be in the same orbit and 180° apart from each other, thereby increasing the frequency of coverage.

Sentinel-2 images cover 13 spectral bands in the visible, near infrared (NIR) and short wave infrared (SWIR) wavelengths, with four bands at 10 m, six bands at 20 m and three bands at 60 m spatial resolution. Table 1 lists the characteristics of the 13 bands. The sensor covers a field of view of 290 km, a swath much wider than the Landsat sensor (185 km) that has been applied widely for global monitoring over the past decades. Hence, the sensor revisits the same area more frequently (every ten days) with a constant viewing angle. The temporal resolution will be further increased to five days with Sentinel-2B. The fine spatial resolution, global coverage

51 and (relatively) fine temporal resolution make the Sentinel-2 data of great utility for a wide range of
 52 applications based on remote sensing.

53

54

Table 1 Characteristics of the 13 bands of Sentinel-2 data

Band number	1	2	3	4	5	6	7	8	8a	9	10	11	12
Center (nm)	443	490	560	665	705	740	783	842	865	940	1375	1610	2190
Width (nm)	20	65	35	30	15	15	20	115	20	20	30	90	180
Spatial resolution (m)	60	10	10	10	20	20	20	10	20	60	60	20	20

55

56 For Sentinel-2 data, four 10 m and six 20 m bands can be used for land-cover/land-use (LCLU) mapping and
 57 change detection. With respect to the three 60 m bands, they are mainly dedicated for atmospheric correction
 58 and cloud screening (i.e., 443 nm blue band for aerosol retrieval and cloud detection, 940 nm NIR band for
 59 water vapor correction, and 1375 nm SWIR band for cirrus detection) (Drusch et al., 2012; Hagolle et al.,
 60 2015). The existence of 10 m bands covering the same scene offers excellent opportunities for downscaling the
 61 20 m bands to 10 m spatial resolution to provide more detailed spatial information. This downscaling issue is
 62 termed image fusion in remote sensing. In this paper, for the first time, we fuse the four 10 m and six 20 m
 63 bands to produce a complete set of ten-band Sentinel-2 data at 10 m spatial resolution and identify the most
 64 accurate image fusion method for this task from the existing approaches.

65 There are two main families of image fusion approaches, that is, component substitution (CS) and
 66 multiresolution analysis (MRA) (Vivone et al., 2015). The CS approach transforms the original multispectral
 67 image into a new domain and substitutes one of the components with the fine spatial resolution band (hereafter,
 68 fine band), such as the panchromatic (PAN) band in PAN-sharpening. Common CS examples include
 69 principal component analysis (PCA) (Shettigara, 1992), intensity-hue-saturation (IHS) (Tu et al., 2001),
 70 Brovey transformation (BT) (Gillespie et al., 1987), Gram-Schmidt (GS) transformation (Laben & Brower,
 71 2000), adaptive GS (GSA) (Aiazzi et al., 2007), and partial replacement adaptive component substitution
 72 (PRACS) (Choi et al., 2011). In the MRA approach, spatial detail is injected by multiresolution decomposition

73 of the fine band. Algorithms falling into this type are high-pass filtering (HPF) (Chavez et al., 1991),
74 smoothing filter-based intensity modulation (SFIM) (Liu, 2000), decimated wavelet transform using an
75 additive injection model (Indusion) (Khan et al., 2008), *a trous* wavelet transform (ATWT) (Vivone et al.,
76 2014), ATWT using the Model 2 (ATWT-M2) (Ranchin & Wald, 2000) and Model 3 (ATWT-M3) (Ranchin
77 & Wald, 2000), and the generalized Laplacian pyramid with modulation transfer function-matched filter
78 (MTF-GLP) (Aiazzi et al., 2006; Vivone et al., 2015).

79 Geostatistical approaches based on kriging have also been explored for image fusion, including kriging with
80 external drift (KED) (Sales et al., 2013), downscaling cokriging (DSCK) (Atkinson et al., 2008;
81 Pardo-Iguzquiza et al., 2006, 2011) and the recently developed area-to-point regression kriging (ATPRK)
82 approach (Wang et al., 2015a,b). They have the significant advantage of preserving the spectral properties of
83 the observed coarse images, that is, they are coherent. The geostatistical solutions treat the coarse bands as
84 primary variables and the fine bands as auxiliary variables. DSCK requires cross-semivariogram modeling
85 which involves complex deconvolution and convolution calculation processes. KED simplifies the
86 semivariogram modeling process and makes downscaling easier to automate. However, the size of kriging
87 matrices in KED is larger than that in ATPRK, and KED requires calculation of the kriging weights locally for
88 each fine pixel. By contrast, ATPRK separates “trend” estimation (i.e., the regression part) from residual
89 downscaling, and the kriging weights are calculated only once. ATPRK is, thus, computationally more
90 efficient than KED and more user-friendly than DSCK (Wang et al., 2015a,b). As the advantages of ATPRK
91 over KED and DSCK have been clearly presented both theoretically and experimentally in our previous works
92 (Wang et al., 2015a,b), KED and DSCK were not considered for downscaling Sentinel data in this paper.

93 The existing CS and MRA approaches were developed originally for image fusion with a single fine band
94 (such as the PAN band in PAN-sharpening). In Sentinel-2, there are *four* 10 m bands treated as such fine bands.
95 Thus, the image fusion task for Sentinel-2 is different from, and more complex than, the conventional
96 PAN-sharpening task. In this paper, the main aim was to extend the CS and MRA approaches to fusion of the
97 Sentinel-2 10 m and 20 m bands. With respect to the advanced ATPRK approach, it can make use of all fine

98 bands straightforwardly by a one-stage multiple regression, and can be applied readily for Sentinel-2 image
99 fusion. The objectives of this paper were, thus, as follows.

- 100 1) To extend the existing CS and MRA approaches to fuse Sentinel-2 10 m and 20 m bands. This was
101 achieved by producing a single band from the four fine bands, and an effective scheme was identified.
- 102 2) To apply ATPRK for fusion of Sentinel-2 data. ATPRK was used straightforwardly for the fusion
103 problem by using all fine bands simultaneously, but also extended by using single band-based schemes.
- 104 3) To compare the three types of image fusion approaches (i.e., CS, MRA and ATPRK) and to identify the
105 most accurate image fusion method for the Sentinel-2 fusion task.

106 The remainder of this paper is organized as follows. Section 2 first introduces the studied data, followed by
107 the principles of the ATPRK approach and the scheme for extending CS, MRA and ATPRK for Sentinel-2
108 image fusion. The experimental results are provided in Section 3, in which the three types of image fusion
109 approaches are compared. Section 4 further discusses the Sentinel-2 image fusion issue and the results, and
110 Section 5 finally concludes the paper.

111

112

113 2. Methods

114

115 2.1. Data

116

117 The first Sentinel-2 products acquired on 18 August 2015 are released online. They are Level-1C products
118 and provide geo-coded top of atmosphere reflectance with a sub-pixel multispectral registration ([Drusch et al.,
119 2012](#)). Each product is a tile of 109 km by 109 km area in the UTM/WGS84 projection.

120 In this paper, we analyzed three datasets. The first one covers a scene in Verona, Italy, the second one covers
121 a scene in Treviso, Italy, and the third one covers a scene in Malmo, Sweden. For each dataset, we selected an
122 area with a spatial extent of 24 km by 24 km. The 20 m bands, thus, contain 1200 by 1200 pixels and the 10 m

bands contain 2400 by 2400 pixels. Fig. 1 shows the three Sentinel-2 images. The three study areas are covered mainly by a mix of vegetation and urban fabric. As shown in the three sub-areas in Fig. 1(j)-Fig. 1(l), the 20 m images are visually more ambiguous than the 10 m images, and many textures evident in the 10 m images cannot be resolved in the 20 m images. This motivates downscaling the 20 m Sentinel-2 bands. The geometric registration between the 10 m and 20 m bands is critical in image fusion and the registration errors will potentially affect the accuracy greatly. For 20 m VNIR bands 5, 6, 7 and 8a of the Level-1C products, the correlation coefficient (CC) between them and the 10 m VNIR bands can reach 0.99, suggesting that the registration of the Level-1C products is highly reliable. Thus, no further registration was performed.

Naturally, the six 20 m bands can be fused with the four 10 m bands to produce ten-band 10 m Sentinel-2 images. In this case, however, no reference at 10 m can be used to examine the downscaling methods objectively. Thus, synthetic datasets (i.e., spatially degraded datasets) were used for reliable assessment and objective comparison between the image fusion approaches. More precisely, convolved with the pre-determined point spread function (PSF), the available 20 m bands and 10 m bands were first upscaled to 40 m and 20 m, respectively. Image fusion was then applied to the observed six 40 m coarse bands, treating the four 20 m bands as fine bands. The produced six-band 20 m fusion results were compared to the original 20 m bands (i.e., the perfect reference) for objective evaluation. This is a scheme used commonly in experimental studies to evaluate downscaling approaches (Atkinson, 2009).

(d)-(f) are 20 m data (1200 by 1200 pixels, bands 12, 8a and 5 as RGB) for Verona, Treviso and Malmo, respectively. (g)-(i) are sub-areas with 200 by 200 pixels in (a)-(c). (j)-(l) are three corresponding sub-areas with 100 by 100 pixels in (d)-(f).

160 2.2. ATPRK

161

162 ATPRK was first proposed for fusion of 500 m MODIS bands 3-7 with 250 m bands 1-2 in our previous
 163 research (Wang et al., 2015a). The approach consists of regression-based overall “trend” estimation (trend is a
 164 term used in geostatistics to refer to the spatially varying mean of a spatial process) and area-to-point
 165 (ATPK)-based residual downscaling (where residual refer to the variation remaining after removal of the trend)
 166 (Atkinson, 2013; Kerry et al., 2012; Kyriakidis, 2004; Kyriakidis & Yoo, 2005). ATPRK can be viewed as an
 167 extension of either regression kriging (Hengl et al., 2004, 2007) or ATPK (Wang et al., 2015a). It is a fast and
 168 user-friendly approach. Inheriting the advantages of ATPK, ATPRK accounts *explicitly* for size of support
 169 (pixel), spatial correlation, and PSF of the sensor. Importantly, it has the appealing advantage that it can
 170 precisely preserve the spectral properties of the original coarse data, that is, it is perfectly coherent. The proof
 171 of perfect coherence of ATPRK can be found in Appendix A in Wang et al. (2015a), which is based on the
 172 perfect coherence of ATPK (see Pages 267-269 in Kyriakidis (2004)). The coherence characteristic of ATPK
 173 and ATPRK is not affected by the specific form of PSF (Kyriakidis, 2004; Wang et al., 2015a).

174 The principle of ATPRK is briefly introduced in this section. Suppose $Z_v^l(\mathbf{x}_i)$ is the random vector (i.e.,
 175 brightness value) of pixel V centered at \mathbf{x}_i ($i=1, \dots, M$, where M is the number of pixels) in coarse band l
 176 ($l=1, \dots, 6$), and $Z_v^k(\mathbf{x}_j)$ is the random vector of pixel v centered at \mathbf{x}_j ($j=1, \dots, MF^2$, where $F=2$ is the spatial
 177 resolution ratio between the coarse and fine spatial resolution bands) in fine band k ($k=1, \dots, 4$). ATPRK aims
 178 to predict the target variable $Z_v^l(\mathbf{x})$ for all fine pixels in all six coarse bands.

179 Let $\hat{Z}_{v1}^l(\mathbf{x})$ and $\hat{Z}_{v2}^l(\mathbf{x})$ be the predictions of the regression and the ATPK parts, respectively. The ATPRK
 180 prediction is given by

$$181 \quad \hat{Z}_v^l(\mathbf{x}) = \hat{Z}_{v1}^l(\mathbf{x}) + \hat{Z}_{v2}^l(\mathbf{x}). \quad (1)$$

182 At a specific location \mathbf{x}_0 , the regression prediction is calculated as a linear combination of the four fine
 183 pixels in the corresponding four fine bands

184
$$\hat{Z}_{v1}^l(\mathbf{x}_0) = \sum_{k=0}^4 a_k^l Z_v^k(\mathbf{x}_0), Z_v^0(\mathbf{x}_0) = 1. \quad (2)$$

185 Based on the assumption of scale-invariance, the coefficients $\{a_k^l | k = 0, \dots, 4\}$ in (2) are calculated according
 186 to the relationship between the observed coarse band l and the upscaled bands Z_v^k ($k=1, \dots, 4$) (created by
 187 convolving the fine band with the pre-determined PSF) from the original four fine bands

188
$$Z_v^l(\mathbf{x}) = \sum_{k=0}^4 a_k^l Z_v^k(\mathbf{x}) + R_v^l(\mathbf{x}), Z_v^0(\mathbf{x}) = 1 \quad \forall \mathbf{x} \quad (3)$$

189 where $R_v^l(\mathbf{x})$ is a residual term and the coefficients are estimated by ordinary least squares.

190 After regression modeling, ATPK is performed in the second-stage to downscale the coarse residuals $R_v^l(\mathbf{x})$
 191 in (3) to the desired fine spatial resolution. ATPK-based residual downscaling retains the spectral information
 192 in the original coarse data. The fine residual at location \mathbf{x}_0 is calculated as

193
$$\hat{Z}_{v2}^l(\mathbf{x}_0) = \sum_{i=1}^N \lambda_i R_v^l(\mathbf{x}_i), \text{ s.t. } \sum_{i=1}^N \lambda_i = 1 \quad (4)$$

194 in which λ_i is the weight for the i th coarse residual centered at \mathbf{x}_i and N is the number of neighboring coarse
 195 pixels. The weights $\{\lambda_i | i = 1, \dots, N\}$ are calculated according to the kriging matrix

196
$$\begin{bmatrix} \gamma_{VV}^l(\mathbf{x}_1, \mathbf{x}_1) & \dots & \gamma_{VV}^l(\mathbf{x}_1, \mathbf{x}_N) & 1 \\ \vdots & & \vdots & \vdots \\ \gamma_{VV}^l(\mathbf{x}_N, \mathbf{x}_1) & \dots & \gamma_{VV}^l(\mathbf{x}_N, \mathbf{x}_N) & 1 \\ 1 & \dots & 1 & 0 \end{bmatrix} \begin{bmatrix} \lambda_1 \\ \vdots \\ \lambda_N \\ \theta \end{bmatrix} = \begin{bmatrix} \gamma_{vV}^l(\mathbf{x}_0, \mathbf{x}_1) \\ \vdots \\ \gamma_{vV}^l(\mathbf{x}_0, \mathbf{x}_N) \\ 1 \end{bmatrix} \quad (5)$$

197 where $\gamma_{VV}^l(\mathbf{x}_i, \mathbf{x}_j)$ is the coarse-to-coarse semivariogram between coarse pixels centered at \mathbf{x}_i and \mathbf{x}_j in band
 198 l , $\gamma_{vV}^l(\mathbf{x}_0, \mathbf{x}_j)$ is the fine-to-coarse semivariogram between fine and coarse pixels centered at \mathbf{x}_0 and \mathbf{x}_j in
 199 band l , and θ is the Lagrange multiplier. Let \mathbf{s} be the Euclidean distance between the centroids of any two
 200 pixels and $h_v^l(\mathbf{s})$ be the PSF of the sensor. $\gamma_{VV}^l(\mathbf{s})$ and $\gamma_{vV}^l(\mathbf{s})$ are calculated by convoluting the fine-to-fine
 201 semivariogram $\gamma_{vv}^l(\mathbf{s})$ with the PSF $h_v^l(\mathbf{s})$ as follows

202
$$\gamma_{vV}^l(\mathbf{s}) = \gamma_{vv}^l(\mathbf{s}) * h_v^l(\mathbf{s}) \quad (6)$$

$$\gamma_{VV}^l(\mathbf{s}) = \gamma_{vv}^l(\mathbf{s}) * h_V^l(\mathbf{s}) * h_V^l(-\mathbf{s}) \quad (7)$$

where $*$ is the convolution operator. $\gamma_{vv}^l(\mathbf{s})$ is estimated by deconvolution of the coarse semivariogram calculated from the coarse residual image $R_V^l(\mathbf{x})$. Details on the deconvolution approach can be found in Wang et al. (2015a,b). The sensor PSF is assumed to be the Gaussian filter in (8), which is commonly used in remote sensing

$$h_V(\mathbf{x}) = \begin{cases} \frac{1}{2\pi\sigma^2} \exp\left[-\left(\frac{x_1^2 + x_2^2}{2\sigma^2}\right)\right], & \text{if } \mathbf{x} \in V(\mathbf{x}) \\ 0, & \text{otherwise} \end{cases} \quad (8)$$

in which σ is the standard deviation (width of the Gaussian PSF), x_1 and x_2 are coordinates of location \mathbf{x} (i.e., $\mathbf{x} = \{x_1, x_2\}$), $V(\mathbf{x})$ is the spatial neighborhood of the pixel centered at \mathbf{x} . In this paper, the width of the Gaussian PSF was set to half of the pixel size.

2.3. Image fusion for Sentinel-2

In this paper, for Sentinel-2 image fusion, we consider four CS methods, including adaptive BT (BTA) (Gillespie et al., 1987, Aiazzi et al., 2007), GSA (Aiazzi et al., 2007), context-adaptive GSA (GSA-CA) (Aiazzi et al., 2009) and PRACS (Choi et al., 2011)). We also consider four MRA methods, including ATWT-M3 (Ranchin & Wald, 2000), MTF-GLP (Aiazzi et al., 2006; Vivone et al., 2015), MTF-GLP with context-based decision (MTF-GLP-CBD) (Alparone et al., 2007), and MTF-GLP with high-pass modulation (MTF-GLP-HPM) (Aiazzi et al., 2003).

CS and MRA use a single fine band (e.g., PAN band) to sharpen the coarse bands. This means that a single band needs to be extracted from the four fine bands in Sentinel-2 data. This issue in image fusion has been conceptualized as “hyper-sharpening” in the very recent literature, which originally means fusion of a fine spatial resolution multispectral image with a coarse hyperspectral image (Selva et al., 2015). For accommodation of fine spatial resolution information from multiple fine bands, two schemes were proposed in

226 [Selva et al. \(2015\)](#), that is, the synthesized band scheme and the selected band scheme. The selected band
227 scheme selects a fine band from the fine band set for each coarse band, which is determined as the one with the
228 largest correlation with the visited coarse band.

229 The synthesized band scheme synthesizes a single fine band from the fine band set (i.e., fine multispectral
230 image), such as averaging all fine multispectral bands ([Selva et al., 2015](#)). However, the synthesized band
231 scheme based on the simple averaging process fails to consider the relation between the visited coarse band
232 and the four fine bands. In this paper, to fully account for the information in the four fine bands, the
233 synthesized band for each coarse band is determined adaptively as a linear combination of the four fine bands.
234 The weights are calculated according to the multiple regression model built between the visited coarse band
235 and the four fine bands. This is a process similar to that in (2) and (3) in ATPRK.

236 For the fusion of Sentinel-2 images, this paper extends the three types of image fusion approaches (i.e., CS,
237 MRA and ATPRK) using the synthesized and selected band schemes. Based on the multiple regression model
238 in (3), the use of the synthesized band in ATPRK amounts to the use of all four fine bands directly. The
239 performances of the three types of approaches coupled with the two band extraction schemes are illustrated in
240 the following experiments.

241

242

243 **3. Experiments**

244

245 *3.1 Experiment on the spatially degraded datasets*

246

247 Four indices were used for quantitative evaluation, including the CC, universal image quality index (UIQI)
248 ([Wang & Bovik, 2002](#)), relative global-dimensional synthesis error (ERGAS) ([Ranchin & Wald, 2000](#)), and
249 spectral angle mapper (SAM). For CC and UIQI, they were first calculated for each band, and then the values
250 for all bands were averaged. For SAM, values for the spectra of all pixels were first calculated and then

251 averaged. As mentioned in Wald et al. (1997), in image fusion, it is important that any synthetic image, once
 252 degraded to its original spatial resolution, should be as close as possible to the original image. Thus, we also
 253 used CC, UIQI, ERGAS and SAM to evaluate the consistency. The fused image was upscaled to the original
 254 coarse spatial resolution and the observed coarse image was used as reference. In the upscaling process,
 255 exactly the same PSF (i.e., the Gaussian filter in (8)) used for simulating the 40 m and 20 m images and
 256 creating Z_V^k ($k=1, \dots, 4$) in the regression modeling in (3) should be used. That is, the PSF should be consistent.

257 Figs 2-4 show the downscaling results for three sub-areas of the three datasets. Note that for each method,
 258 the band extraction scheme leading to the greatest accuracy is shown. For MRA and ATPRK, the results are
 259 those obtained with the synthesized bands. For CS, the results are obtained with the selected bands (except
 260 BTA for the Malmo data and PRACS for the Treviso data). The selected bands for the three datasets are
 261 displayed in Table 2. For the coarse bands, the selected fine bands generally have the closest wavelengths with
 262 them. For example, for the VNIR bands 6 (733-748nm), 7 (765-785nm) and 8a (855-875nm), the spectrally
 263 closest band 8 (785-900nm) is selected.

264

265 Table 2 The selected fine band (bands 2, 3, 4 or 8) for each coarse band (bands 5, 6, 7, 8a, 11 or 12) of the three datasets

	Band 5	Band 6	Band 7	Band 8a	Band 11	Band 12
Verona	Band 4	Band 8	Band 8	Band 8	Band 4	Band 4
Treviso	Band 4	Band 8	Band 8	Band 8	Band 4	Band 4
Malmo	Band 3	Band 8	Band 8	Band 8	Band 3	Band 4

266

267 It can be seen that the BTA result in Fig. 4(d), GSA result in Fig. 4(e) and GSA-CA result in Fig. 4(f) lead to
 268 obvious spectral distortion. This is clearly illustrated by the results for road restoration. PRACS and
 269 ATWT-M3 produce over-smooth results, in which the texture (e.g., the elongated features in urban areas)
 270 cannot be observed very clearly, see Fig. 2(g), Fig. 2(h), Fig. 3(h) and Fig. 4(h). The MTF-GLP-CBD results
 271 tend to be superior to MTF-GLP and MTF-GLP-HPM, and are closest to ATPRK results. Tables 3-5 list the
 272 quantitative assessment for the three datasets at the target fine spatial resolution. Three observations can be
 273 made from the comparisons.

274 First, for the CS methods, greater accuracies are produced when the selected band scheme is used. For

275 example, for the Verona data, the CC values of GSA and GSA-CA increase by 0.007 and 0.003 using the
276 selected band scheme. Moreover, the GSA and GSA-CA methods are more accurate than BTA and PRACS.

277 Second, for the MRA and ATPRK methods, the synthesized band scheme is able to produce greater
278 accuracies than the synthesized band scheme. MRA (except ATWT-M3) with the synthesized band is superior
279 to CS with the selected band. Furthermore, the general rank of the four MRA methods in terms of accuracy
280 (from most to least accurate) are MTF-GLP-CBD, MTF-GLP, MTF-GLP-HPM and ATWT-M3. The
281 advantages of the former three methods over ATWT-M3 are obvious. More precisely, for all three datasets, the
282 CC values of the three MRA methods are at least 0.01 larger than that of ATWT-M3, and the gains in UIQI are
283 even larger (e.g., over 0.02 for the Treviso data).

284 Third, given the same scheme of band extraction for all methods, ATPRK produces the greatest accuracy
285 amongst the three types of approaches. Take the synthesized band scheme as an example, ATPRK produces
286 the largest CC (0.9932, 0.9916 and 0.9963 for Verona, Treviso and Malmo, respectively) and UIQI (0.9931,
287 0.9914 and 0.9963 for Verona, Treviso and Malmo, respectively) and smallest ERGAS (1.5374, 1.7618 and
288 1.3456 for Verona, Treviso and Malmo, respectively) and SAM (0.0217, 0.0237 and 0.0198 for Verona,
289 Treviso and Malmo, respectively) for all three datasets.

290 Tables 6-8 present the consistency of the downscaling methods for the three datasets at coarse spatial
291 resolution. Consistency was used here because it was demonstrated to be able to give reliable assessment of
292 the relative performance of image fusion and to be superior to the commonly used quality no reference (QNR)
293 metrics (Palsson et al., 2016). The three MRA methods, including MTF-GLP-CBD, MTF-GLP,
294 MTF-GLP-HPM, outperform all four CS methods. It is worth noting that ATPRK achieves the ideal CC and
295 UIQI and almost ideal ERGAS and SAM for all three datasets, demonstrating that it can perfectly preserve the
296 spectral properties of the original coarse data.

3.2 Experiment on real datasets

From the test in section 3.1, it is evident that ATPRK with the synthesized band can produce more accurate results than the other methods. In this experiment, we fused the original 20 m band 10 m data using the ATPRK with the synthesized band approach. The 10 m downscaling results for the three datasets are shown in Figs 5-7, where each figure show results for three sub-areas. We visually compare the 10 m results with the original 20 m images. It can be seen clearly that by borrowing the 10 m information from the four-band 10 m data, more explicit information can be presented. The small patches, boundaries of classes and textural information (e.g., elongated features) are shown more clearly in the 10 m downscaling results. Moreover, the spectral information of the 20 m data is accurately retained.

4. Discussion

Sentinel-2 provides six bands (5, 6, 7, 8a, 11 and 12) with a spatial resolution of 20 m, and only four bands (2, 3, 4 and 8) at the finer spatial resolution of 10 m. It is, therefore, a natural task to take full advantage of the spatial information in the four 10 m bands to downscale the six 20 m bands to the finer spatial resolution, to provide users with more detailed information in the six bands, and create a complete set of 10 bands with a fine spatial resolution of 10 m. This paper achieves this important objective by extending eight existing image fusion approaches (i.e., CS and MRA), and the recently developed ATPRK approach, to the specific Sentinel-2 image fusion issue.

Fusing the six Sentinel-2 20 m bands with the four 10 m bands is different from the conventional PAN-sharpening problem where a single PAN image is available as the reference for several coarse multispectral bands. This paper, thus, extends eight CS and MRA approaches to make them suitable for Sentinel-2 image fusion via two schemes, the synthesized band and selected band schemes. The extended versions were tested in the experiments and their performances were also compared to the advanced ATPRK approach. It was shown that the bands 5, 6, 7, 8a, 11 and 12 downsampled to 10 m were visually clearer than the 20 m bands, and greater spatial detail (e.g., small patches and elongated features) was reproduced. This will certainly increase the utility of these six bands in a greater number and range of applications. For example, as shown in Fig. 5(f), Fig. 6(d) and Fig. 7(d), the urban fabric can be observed much more clearly after image fusion. The encouraging results will motivate the utility of these six downsampled bands in urban mapping.

Experimental comparison between the three types of approaches revealed the advantages of ATPRK for the fusion of Sentinel-2 images: ATPRK reproduces accurate spatial textures and preserves perfectly the spectral properties of the original coarse data. The quantitative assessment illustrated that ATPRK consistently produces greater accuracies than all of the CS and MRA approaches. In addition, for ATPRK, the synthesized band scheme can produce more accurate fusion results than the selected band scheme, suggesting that the former band extraction scheme is a preferable choice for ATPRK-based Sentinel-2 image fusion.

445 This paper provides the first guidance (including the option of the band extraction scheme and the image
446 fusion approach) for fusion of Sentinel-2 images. Applying the image fusion approaches to freely available
447 multi-temporal Sentinel-2 images, ten-band 10 m time-series products will be produced. Appreciating the
448 wide swath and frequent revisit capabilities, such 10 m products will show great potential for dynamic LCLU
449 monitoring and change detection at the global scale. For example, bands 3 (centered at 560 nm) and 11
450 (centered at 1610 nm) of Sentinel-2 can be used to calculate the Normalized Difference Snow Index (NDSI)
451 and Modified Normalized Difference Water Index (MDNWI) (Xu, 2006), which can extract snow-covered
452 areas and water bodies (e.g., inland water in urban areas) on the Earth, respectively. In the original Sentinel-2
453 data, however, they are at different spatial resolutions (10 m for bands 3 and 20 m for band 11). The fused
454 ten-band 10 m Sentinel-2 dataset offers compatibility to calculate the NDSI and MDNWI at 10 m, a spatial
455 resolution finer than that of the original band 11.

456 The ten-band 10 m time-series products will offer excellent opportunities for blending with the forthcoming
457 Sentinel-3 data (Berger & Aschbacher, 2012; Donlon et al., 2012; Verhoef & Bach, 2012). The Sentinel-3
458 mission aims to provide fine temporal resolution (<2 days) data for timely monitoring. The 21 bands for the
459 task (i.e., the Ocean and Land Colour Instrument (OLCI) bands), however, are provided at a coarse spatial
460 resolution of 300 m. The ten-band 10 m Sentinel-2 data can be blended with the Sentinel-3 data to generate
461 time-series data at both fine temporal resolution (<2 days) and spatial resolution (10 m). Specifically, bands 5,
462 6, 7 and 8a of Sentinel-2 correspondingly have close wavelength as OLCI bands 11, 12, 16 and 17 of
463 Sentinel-3. With the approaches developed in this paper, Sentinel-2 will be able to provide important reference
464 data with a spatial resolution of 10 m for the 300 m OLCI bands 11, 12, 16 and 17 of Sentinel-3. It is worth
465 noting that, if achievable, the 10 m time-series data produced by blending Sentinel-2 with Sentinel-3 data
466 would have appealing advantages in terms of spatial resolution in comparison with the 30 m data produced by
467 blending Landsat and MODIS data (Gao et al., 2006, 2015; Zhu et al., 2010). This will be an important topic
468 for future research in remote sensing.

For the Sentinel-2 mission, the required signal-to-noise ratio (SNR) for bands 5, 6, 7, 8a, 11 and 12 can be achieved only at a spatial resolution coarser than 10 m (i.e., 20 m in the products). This necessitates the investigation of the relation between the SNR of the 10 m fused images and the original 20 m images. We approximately calculated the SNR of an image based on the ratio of the mean value to the standard deviation of the image. Table 9 lists the reduction in SNR for each band after image fusion for the three datasets, where the ATPRK method with the synthesized band scheme was used. The SNR reduction is a function of the study area and sharpened band of interest. Generally, the reduction is smaller than 10%. The reduction in SNR is a cost of sharpening the 20 m bands.

Table 9 The percentage of SNR reduction after downscaling bands 5, 6, 7, 8a, 11 and 12 based on ATPRK with the synthesized band scheme

	Band 5	Band 6	Band 7	Band 8a	Band 11	Band 12
Verona	10.94%	9.67%	8.88%	8.15%	7.66%	10.52%
Treviso	12.73%	9.62%	9.10%	8.55%	8.87%	13.44%
Malmö	5.14%	6.85%	7.18%	7.01%	3.44%	4.69%

This paper is the first to downscale Sentinel-2 bands from 20 m to 10 m spatial resolution. The proposed approaches were tested with three 24 km by 24 km datasets. It is encouraged to test further cases (e.g., datasets with larger size) in future research, to provide a more comprehensive comparison of the available image fusion approaches. Moreover, in addition to the synthesized and selected bands schemes, it is of great interest to develop new alternatives to make full use of the four 10 m bands of Sentinel-2.

The 30 m Landsat 8 operational land imager (OLI) data have been used widely for global monitoring. By pan-sharpening, the OLI data can be increased to a finer spatial resolution of 15 m (Zhang & Roy, 2016). Such a resolution is coarser than 10 m that can be achieved by the new Sentinel-2 data associated with an image fusion approach. Such a difference in spatial resolution (i.e., 5 m) may be critical for identifying small targets, such as residential buildings and roads. In addition, it would be interesting to conduct a systematic study on pan-sharpening Landsat 8 OLI data based on the three types of image fusion approaches (e.g., CS, MRA and ATPRK) investigated in this paper.

5. Conclusion

In this paper, the six 20 m bands of Sentinel-2 were downscaled to 10 m with the aid of the four 10 m bands of the same satellite sensor. The existing CS- and MRA-based image fusion approaches and the recently developed ATPRK approach were all developed for this downscaling problem. To use the fine spatial resolution from the four 10 m bands, two schemes, the synthesized band scheme and the selected band scheme, were considered to obtain a single fine resolution band for matching with each 20 m multispectral image or 20 m band. The generic findings from the three case studies on downscaling Sentinel-2 images are summarized as follows.

- 1) For ATPRK or a MRA-based method, the synthesized band scheme is able to produce greater accuracies than the selected band scheme (Tables 3-5). For a CS-based method, however, the selected band scheme tends to be more accurate.
- 2) MRA methods (except ATWT-M3) are superior to CS methods. For the Malmo data, the CC values of MRA methods are above 0.99, but the CC values of CS methods are below 0.99.
- 3) Given the same scheme of band extraction, ATPRK can produce more accurate results than the CS and MRA approaches (Tables 3-5). That is, ATPRK with the synthesized band is the most accurate method amongst the three groups of approaches. Using the synthesized band, the UIQI of ATPRK is 0.032, 0.008, 0.005 and 0.010 larger than ATWT-M3, MTF-GLP, MTF-GLP-CBD and MTF-GLP-HPM for the Treviso data; the ERGAS of ATPRK is 1.5, 0.6, 0.6 and 0.5 smaller than ATWT-M3, MTF-GLP, MTF-GLP-CBD and MTF-GLP-HPM for the Malmo data.
- 4) ATPRK has the property of perfect prediction coherence (almost ideal CC, UIQI, ERGAS, and SAM are achieved in Tables 6-8).
