### *SPECTRAL* MEASUREMENTS OF HOT ELECTRONS PROM LASER-PRODUCED PLASMAS\*

#### G. L. Cano, P. J. Brannon, J. E. Powell Sandia Laboratories, Albuquerque, NM 87115

#### ABSTRACT

Snectral measurements have been made of electrons emanating from CD<sub>2</sub> and LiD plasmas produced in the multiple-beam laser experiments at Sandia Laboratories. Spherical CD<sub>2</sub>, LiD and LiDT pellets were irradiated in a tetrahedral geometry with energies up to 50 J/beam in one nsec from a Nd:glass laser system. The electron spectral measurements were done with a magnetic spectrometer in the energy range *50~l60 keV.* The spectra obtained are a aonotonically decreasing function of intensity with increase in kinetic energy.

## DiTRODUCTIOH

Only a relatively small number of papers are found in the open literature dealing with experimental determinations or theoretical calculations of the electron spectral emission from laser-produced plasmas. Yet, there has been a need to establish whether or not hot electrons are an important energy sink. Thus, one of the laser-plasma experiments done at Sandia Laboratories, in which spherical solid targets were irradiated in a tetrahedral geometry, addressed this subject. Spherical CD<sub>2</sub>, LiD and LiDT targets were irradiated with the four beams from the Ndiglass laser system. The pellets ranged is diameter from 50 to 200 *m* and were irradiated with a pulse of width equal to 0.97 nsec FWHM and of energy up to 50 J/beam.  $\mu_{1/2}$  2 The maximum bower density on the berrefs was  $\sim$  to  $\sim$  w/cm . In general,  $-7$ the pellets were irradiated in a background pressure of 2  $\times$  10<sup>-1</sup> Torr. However, data also were obtained using CD<sub>o</sub> targets in a background of

deuterium gas ranging in pressure from 0.1 to 10 Torr.

## LASER

The Sandia 4-beam laser system has already been described on other occasions and more will be said about it in a later paper. Thus, I will not discuss it here.

## EXFERBENTAL HARDWARE

Insofar as experimental hardware is concerned, the experiment was done by means of a magnetic spectrometer and PIN-diode solid state detectors. Slide I shows an overall view of the experiments chamber and

\*

 $-2-$ 

includes the 8-spectrometer. The distance from the plasma source at the denter of the chamber to the entrance aperture of the spectrometer was about  $65$  cm. This aperture was  $0.5$  cm x 1.0 cm. The total distance from plasma source to detectors was approximately 1 meter. Slide 2 shows a close-up view of the cult (describe setup).

Slide 3. This slide shows a cross-sectional view of the  $\beta$  spectrometer. The overall size is 23 em x 51 cm x 25 cm and contains about 50 lbs of magnets. The magnetic field, 128 gauss, is uniform to  $\sim$  l gauss over an area 15 cm *x* 33 cm, and the analyzing region Is well within this area . Electrons and ions enter the magnetic field through the  $0.5$  cm<sup>2</sup> aperture. The ions proceed into a "get-lost " hole *or* an ion detector placed on a port directly across from the entrance aperture. Electrons, because of their lower magnetic rigidity, follow orbit paths, as given by well-known laws relating to magnetic fields ani energetic charged particles, to the

appropriate detector placed along a line parallel to and colinear with the entrance aperture. Ten detectors were utilized in the spectral measurements. Halfway along the orbit is placed an orbit ^defining aperture 1 cm wide x 11 cm long.

The PIN diode detectors are very sensitive to electromagnetic radiation. Thus, a pinhole-free foil of Al, 0.2  $\mu$ m thick was placed immediately before all the detectors to preclude light from the expanding plasma from getting to them. The effect of this Al foil was later taken into account in determining the g-intensity in each channel. A background detector of the same type but without a foll was located within the spectrometer.

-3-

Thle detector was exposed to scattered light but was out of reach of Scattered electrons (indicate location). *By* placing, on alternate shots, a 350 G magnetic field perpendicular to a line through two beam-defining apertures prior to the entrance into the spectromater, the background noise could be accounted for. Normally, signal to noise ratios of two were obtained.

## RESULTS

Slide 4. This slide shows the relation found between relative 3signal/energy as a function of beta kinetic energy for a given shot. The target was a CD<sub>2</sub> pellet of diameter 100 µm and the total energy in the four beams going ioto the chamber vr.s 130 J. *The* function is monotonic and shows a flattening in the high energy end, and indicates that there

may be a substantial number of electrons of energy  $\leq$  50 keV.

Slide 5. This is a semilog plot similar to the last one. However, this is for an LiD sphere 95  $\mu$ m in diamete:. The energy absorbed was  $85 J$ , as determined from recording the transmitted, scattered and reflected energies. Here is plotted relative intensity/energy versus Kinetic energy. That is, the Al foil has been corrected for. The relation is also monotonic and indicates much higher numbers of betas below 50 keV than above.

Slide 6. The three curves shown on this slide are for  $CD_{p}$  targets. The cne with the uncertainties indicated is the same one shown two slides back, but now corrected for the *AX* foil- *The* dominant effect of this was to raise the low energy end  $w/r$  to the high energy side. The other two

**J**+

By integrating the 9-intensities/energy for a typical shot, it was established that the total number of betas coming from the laser-produced plasma in the energy range 50 to 150 keV, assuming isotropic emission, was of the order of  $10^{10}$ . The total kinetic energy carried by these electrons; again assuming isotropy, was  $\sim$  l mj of the absorbed energy. It must be mentioned that hot electrons did not occur on every shot. In fact, they appeared in only about  $1/2$  of the shots for CD<sub>2</sub> and about  $1/3$  for LiD, and not at all for LiDT.

In summary and conclusion, spectral measurements were made of electrons emanating from CD<sub>p</sub> and LiD laser-produced plasmas. No electrons in this energy range were observed coming from LiDT and only in about 1/2 of the shots for CD<sub>2</sub> and 1/3 for LiD. Possible reasons for this are nonuniformities in the four beam intensities, but more probably it was due to oxygen and other impurities, as Ar, in LiD and LiDT as preparation  $\cdot$ of the pellets for irradiation was done in an Ar atmosphere.

**1-lnes are** for CDg pellets irradiated in a deuterium, background gas of pressure as indicated. The pellets were bigger than on previous shots shown and the energy absorbed was larger. Why the shape of the curves are different with and without a background gas is not known. The range of a 50 keV electron in a deuterium gas a t t.O *Tbrr* is about 1J meters. *Thus,*  in their path to the detectors 1 meter from the plasma source, the electrons lose <  $10\%$  of their energy to bremstrahlung and to background thermal electrons by coulomb collisions. Also, the fractional energy change for the lower energy electrons would be more than for the higher energy electrons- Thus, the curves should be similar.

The spectra are a monotonically decreasing function of intensity with increase in kinetic energy. In some cases, the distribution appears much like the high energy tail of a Maxwell distribution. The total number of electrons ejected into  $4\pi$  in the energy range studied was of order  $10^{10}$ and contained only  $\sim 1$  all of the absorbed energy.

-5-

Finally, although hot-electron spectral information has been obtained in about 20 shots, it must still be considered preliminary data.
