38055 Grenoble Cedex, France

The structure of  $^{66}\text{Zn}$  has been investigated by studying the yield functions, angular distributions and coincidences of the  $\gamma$ -rays emitted during bombardment of an enriched  $^{64}\text{Zn}$  foil by  $\alpha$  particles of medium energy 27 MeV.

Spins up to 10  $\hbar$  were assigned to observed states.

NUCLEAR REACTIONS  $^{64}\text{Zn}(\alpha, 2n\gamma)^{66}\text{Zn}$ ,  $E_{\alpha} = 22 - 40$  MeV; measured  $\gamma$ ,  $\gamma$ - $\gamma$ ,  $\sigma(E_{\alpha}, \theta_{\gamma})$ , deduced decay scheme and J for high spin states;  $^{66}\text{Zn}$  foil target, Ge(Li) detectors.

## I - INTRODUCTION

The lowest  $J^{\pi} = 9/2^{+}$  states of  $^{65,67}\text{Zn}$  have been observed as  $L = 4$  transfers in the (d,p) reaction on  $^{64,66}\text{Zn}$  at excitation energies of 1.064 MeV and 0.602 MeV respectively, and interpreted as single particle states in which the transferred particle occupies the  $1f_{7/2}$  shell<sup>1</sup>. The neutron  $1g_{9/2}$  shell is thus not far removed in energy from the  $1f_{7/2}$  shell and consequently, among the states at a few MeV excitation in  $^{66}\text{Zn}$  one may expect those whose neutron configurations lead to high spins.

The formation of such states necessitates the transfer of a large angular momentum which may be conveniently achieved by inducing compound nucleus reactions using heavy projectiles. We have verified in several cases that the same high spin states may be formed in the  $f$ - $p$  shell, using  $(\alpha, 2n\gamma)$  reactions or  $(\text{HI}, \text{Zn} \nu \nu \alpha)$  reactions<sup>2,3</sup>. This is readily understandable since the notion of "high spin" in the  $f$ - $p$  shell essentially means  $J^{\pi} \approx 10 \hbar$  and the neutron evaporation removes less angular momentum than that of charged particles. Further the large Doppler effect present in the heavy ion reactions can provide a source of difficulty in measurements of  $\gamma$ - $\gamma$  coincidences and  $\gamma$ -ray angular distributions thus favouring the use of  $\alpha$  projectiles when measurements based on Doppler effect are not required.

## II EXPERIMENTAL PROCEDURE

We have observed  $^{66}\text{Zn}$  by several reactions: principally in the  $^{64}\text{Ni}(\alpha, 2n\gamma)$  and  $^{64}\text{Zn}(\alpha, 2p\gamma)$  reactions using  $\alpha$  particles of 22-40 MeV and subsidiary measurements were also made using the reactions  $^{63}\text{Cu}(\alpha, p\gamma)$  at 22 MeV,  $^{65}\text{Cu}(\alpha, p2n\gamma)$  at 40 MeV,  $^{68}\text{Zr}(\alpha, p2n\gamma)$  at 40 MeV and  $^{56}\text{Fe}(\text{C}, 2p\gamma)$  at 40 MeV. The  $^{64}\text{Ni}(\alpha, 2n\gamma)$  reaction at  $E_{\alpha} = 27$  MeV and 30 MeV was selected for the main study for the following reasons:

(1) At  $E_{\alpha} = 27$  MeV, the  $^{66}\text{Ni}(^4\text{He}, ^4\text{He})^{66}\text{Zn}$  reaction is completely eliminated and the only competing channel is the  $^{66}\text{Ni}(^4\text{He}, ^4\text{He})^{66}\text{Cu}$  reaction in which the deexcitation of the radioactive final nucleus contributes little to  $^{66}\text{Zn}$ . One must avoid significant formation of  $^{66}\text{Zn}$  by other direct reaction channels, thus the  $^{64}\text{Zn}(^4\text{He}, ^4\text{He})^{66}\text{Zn}$  reaction, for example, is excluded for the study of  $^{66}\text{Zn}$  since  $^{66}\text{Cu}$  is mainly produced via the  $(^4\text{He}, ^4\text{He})$  reaction.

(2) Evaporation of neutrons was particularly to be avoided as a consequence of the reasons outlined above. We prefered gamma-ray spectra obtained at  $E_{\alpha} = 30$  MeV for a better yield of the high spin states.

Using beams from the Grenoble cyclotron, and the  $(^4\text{He}, ^4\text{He})$  self-sustained  $^{66}\text{Ni}$  target ( $700 \mu\text{g}/\text{cm}^2$ ) and large volume  $\text{Ge}(\text{Li})$  detectors ( $100 \times 100 \times 3$ ) with a typical resolution of 3 keV at 1.33 MeV, five types of measurements were performed:

- Direct  $\gamma$  spectra and  $\gamma\text{-}\gamma$  coincidences: Direct  $\gamma$  spectra and some gated spectra obtained using a 27 MeV  $\alpha$  beam are shown in Fig. 1; the corresponding levels scheme is presented in Fig. 3. The  $\gamma$  transitions are marked together with certain weak transitions of  $^{66}\text{Zn}$  which are important for confirmation of assigned spin values.

- Excitation functions: Fig. 2 shows the excitation functions for  $\alpha$  energies between 22 and 40 MeV, normalized to the  $(^4\text{He}, ^4\text{He})$  transition which is common to all cascades. The slope of the excitation functions gives an indication of the spin of the level from which the  $\gamma$  ray originated, being larger for higher spin states.

- Angular distributions: the results obtained using a 30 MeV  $\alpha$  beam are presented in table I. It will be noted that the given assignments result in a value of the spin alignment parameter  $\sigma_{\gamma}(J)$  for each level, which remains nearly constant for all transitions to and from the level considered, the corresponding  $\chi^2$  being very close to its minimum value. We further note that, with our assignment

the parameters  $a$  and the spin  $J$  of a given level are related through the relation  $a = a' J + b$  where  $a'$  and  $b$  are positive constants (with one exception for the 627 keV transition).

A delayed  $\gamma$  ray of 341 keV was observed in the  $^{60}\text{Ni}(p,n)^{60}\text{Ni}$  reaction but its  $\lambda_{1/2} = 13.95$  (error  $\pm 1.6 = 50\%$ ) is 11% longer than the value between 6 and 100 ns which is possible. A possible assignment of this transition is a delayed  $\gamma$  ray ( $I_{442} = 42 \pm 2\%$ ) which originates from the 1003 keV level of the function describing the 501 keV level in  $^{60}\text{Ni}$  (Fig. 3) since the calculated half-life of  $\gamma$ -rays is not delayed; the origin of this transition may be found in the possible reaction  $^{64}\text{Ni}(p,n)^{63}\text{Ni}$ . It will be noted that the other delayed transition has been observed in 5 to 100 ns (500 keV).

### III - SUMMARY OF RESULTS

Referring to Fig. 2-3 and Tables I-III we now discuss spin and parity assignments.

The  $2^+$  states at 1039 keV and 1562 keV are well known.

The 2650 keV state: the assignment  $4^+ (5,0,2)$  is confirmed.

The 2765 keV state: this level has been observed in the  $(p,p'n)$  reaction<sup>6</sup> by decay to the  $2_1^+$ ,  $2_2^+$  and  $4_1^+$  states and, with a very weak intensity, in the  $(p,n)$  reaction<sup>9,10</sup> as a possible  $J = (0,1,2)$  state. We exclude these values because of the presence of a 581 keV  $\gamma$ -transition from the  $5^+$  level at 3746 keV (subsequently assigned). A possible assignment consistent with the angular distribution analysis of the 692 keV transition which deexcites this level to the  $2_2^+$  level is  $J = 3^-$ : this state has not been observed in the  $(t,p)$  reaction<sup>11</sup>, thus it may be a  $J^{\pi} = 3^+$  state. It will be noted that, with this assumption, the 581 keV  $\gamma$ -ray is a M2 transition and its intensity seems to be rather too weakly compared to that of the 526 keV transition ( $5^+ \rightarrow 3^+$ ) when we observed them in the  $\gamma$ -ray spectrum gated by the 501 keV transition. Unfortunately the 591 keV  $\gamma$ -ray an-

lar distribution could not be correctly extracted because of the presence of the 868 keV  $\gamma$ -line of  $^{152}\text{Eu}$ . Another possibility is a  $J = 4$  assignment (see Table 7) if we allow a value of  $a$  which does not obey the  $a = a J + b$  relation established for the other spins. With this last assumption the 627 keV ( $6^- \rightarrow 3^-$ ) and 627 keV ( $6^- \rightarrow 4$ )  $\gamma$ -rays may have their identification. Then we are led to the assignment definite  $J$  values to each of the  $2^+$  and  $3^+$  levels which is usually predicted in our experiment.

The 2626 keV state known as the  $3_1^-$  level  $7,11,12,13$  is identified.

The 3077 keV state has been observed as a  $4^+$  level  $7,11,14,15$  but first that this state decays essentially to the  $6_1^+$  level by the 627 keV  $\gamma$ -ray in agreement with Ref. 16, but in disagreement with Ref. 6. The angular distribution analysis of the 627 keV transition allows a  $J = 4$  assignment with correct values of  $a_2$  but too small value of  $a$  referring to the  $a = a J + b$  relation (see Table 1).

The 3746 keV state has been observed in the  $(p,p')$  reaction  $^{17,18}$  and probably in the  $(\alpha,\alpha')$   $^7$  and  $(t,p)$   $^{11}$  reactions but the presence of other levels, very close in energy  $^{18}$ , so far precluded a spin assignment. This level decays principally to the  $6_1^+$  states with the 1266 keV and 604 keV  $\gamma$ -rays which are  $L = 1$  transitions: thus its spin is  $J = 3, 4$  or  $5$ . The  $A_2$  and  $A_4$  values of the angular distribution coefficient exclude the  $J = 4$  assignment and we rule out the  $J = 3$  value for this state since none of the  $2^+$  states is fed from it: we propose  $J = 5$ .

The 4250 keV state decays to the  $J = 5$  level by a cascade of two  $L = 1$   $\gamma$ -rays (176 keV and 320 keV) and by a cross-over  $L = 2$   $\gamma$ -ray (504 keV): we can assign to it the value  $J = 7$  in agreement with the yield functions slopes of the 504 keV and 176 keV  $\gamma$ -rays. Furthermore this level may be identified, with a good energy accuracy, with the  $(7^-)$  state observed in the  $(t,p)$  reaction  $^{11}$ , so that we assign  $J^\pi = 7^-$  to the 4250 keV level. Consequently we exclude a possible parity for the  $J = 5$  state at 3746 keV since the 504 keV  $\gamma$ -ray thus would be a

62 transition and a  $4^+$  state (with  $100\%$  intensity of the  $6^+$   $\beta$  ray) (54 %, 46 %) of the two  $\gamma$  rays (567 keV and 474 keV) which, with the  $7^-$  level, gives in this case a half-life  $1_{1/2} = 39$  ns for the  $7^-$  level and we have not observed the 474 keV  $\gamma$  ray. The  $4^+$  state is not observed but it is well established (19,20) that a  $62^-$  transition cannot be accelerated. Thus we propose  $J^\pi = 5^-$  for the  $6^+$   $\beta$  ray level.

The 4074 keV  $\gamma$  ray decays only to the  $4^+$  state from the 470 keV and 320 keV  $\gamma$  rays and a  $4^+$  transition from the  $6^+$  state of these lines to the  $4^+$  levels allows the exclusion of a possible  $6^+$  state. We assign  $J^\pi = 6^-$  to the 4074 keV  $\beta$  ray.

The 4120 keV  $\gamma$  ray decays only to the  $4^+$  state through a  $4 \rightarrow 2$  transition of 1720 keV; the absence of other lines from this level and the yield function of the 1229 keV  $\gamma$  ray from the  $J^\pi = 4^+$  assignment. In the hypothesis of a negative parity the transition to the  $6^-$  state of 3026 keV should be competitive with the 1229 keV line, even if we take the extreme value of  $10^{-3}$  W.u. for its strength. The absence of a transition to the  $6^-$  state makes the assignment  $J^\pi = 6^+$  more probable.

The 5205 keV is decaying to the  $4^+$  state by a 3026 keV  $\gamma$  ray ( $l = 2$ ) and to the  $7^-$  level by a 555 keV  $\gamma$  ray ( $l = 1$ ); the regular distributions analysis, the yield functions and the branching ratios (54 %, 46 %) of these lines allow a  $J^\pi = 6^+$  assignment.

The 5463 keV state decays only to the  $6^-$  state by the 1213 keV ( $l = 2$ )  $\gamma$ -ray. The absence of transitions to the  $4^+$ ,  $5^+$ ,  $6^+$ ,  $6^-$  states exclude the values  $J = 5, 6, 7$  for this level and the yield function of the 1213 keV line indicate a  $J > 7$ . The value  $J = 8$  may be ruled out since no transition to the  $6^+$  or  $6^-$  was observed. Thus we propose the  $J^\pi = 9^-$  assignment with a negative parity to take into account the fact that the 1213 keV  $\gamma$  ray is not observed (it is not a  $62^-$  transition).

The 628 keV state is mainly characterized by the first  $J^\pi = 2^+$  level in the  $6^+$ . Some considerations than above allow  $J^\pi = 2^+$  or  $4^+$  values. The 508 keV angular distribution analysis, the absence of the  $11^+$  level in the  $7^+$  states, and the relative weakness of the 628 keV transition to the  $5^+$  state are consistent facts which exclude  $J^\pi = 10^-$ . In the  $6^+$  level scheme proposed  $J^\pi = 4^+$  since the 465 keV  $\gamma$ -ray is not observed (Table 2).

#### IV - Discussion

It will be noted that: (i) our spin assignments are well supported by the increase of the g-factor from the  $J^\pi = 2^+$  to  $4^+$  and  $6^+$  levels (see the g-factors  $g_2$  in Table 1) (ii) the reaction  $^{66}\text{Zn}(p, \alpha)^{66}\text{Zn}$  mainly populates the so-called "yrast states": then the  $3^+$  state at 26 keV,  $4^+$  state at 2450 keV and  $5^+$  state at 508 keV are the only states observed, the  $6^+$  at 3077 keV is unusually populated and the  $8^+$  (at 465 keV)<sup>11</sup> and the  $5^+$  (at 3889 keV)<sup>11</sup> are not seen.

It is difficult to obtain a theoretical description of these experimental results due to the large number of particles involved. The closed shells which make any calculation very costly. Thus we first consider the level schemes of the isotonic nuclei  $^{66}\text{Zn}$  and  $^{66}\text{Ge}$ .<sup>11</sup> (Table 2). It may be seen that the observed states common to both nuclei are mainly positive parity. This may indicate that positive parity states are associated with the  $\psi \left[ (1 f_{7/2})^2 (1 g_{7/2})^2 \right]^+$  and negative parity states are associated with the  $\psi \left[ (1 f_{7/2})^2 (1 f_{5/2} + 1 f_{3/2}) \right]^+$  configurations up to  $J^\pi = 2^+$  and  $\psi \left[ (1 f_{7/2})^3 (1 g_{7/2}) \right]^+$  configurations beyond  $J^\pi = 2^+$ . This speculation, based on a few nucleon excitation, is supported by recent diffraction measurements on  $^{66}\text{Zn}$ .<sup>12</sup> The absence of the 465 keV  $\gamma$ -ray ( $J^\pi \rightarrow 5^+$ ) is found to be only 1.5% of the total intensity, that there are no strong collective effects.

A sensitive test of the many functions of nuclear states is provided by the data on radiative lifetime and of ground lifetimes in  $^{106}\text{Zr}$  are known only for the lowest levels  $10, 24$ ; such measurements, by the recoil distance method are foreseen in the near future.

The authors wish to thank Dr. A. Fort, J. G. B. F. L. and P. Tourner for their technical assistance.

Figure Caption

- FIG. 1 Upper part:  $\gamma$  ray spectra of  $^{66}\text{Zn}$  obtained from a  $^{60}\text{Co}$  source and a  $^{66}\text{Zn}$  target with 27 MeV particles. Lower part: Selected spectra observed in coincidence with  $\alpha$  particles in the indicated  $\beta$  regions, and with subtracted background.
- FIG. 2 Excitation functions of the  $\gamma$  rays emitted between  $^{66}\text{Zn}$  levels populated in the  $^{64}\text{Ni}(\alpha, 2n)^{66}\text{Zn}$  reaction. Intensities are normalized to the 1039 KeV transition. The 1279 KeV  $\gamma$  ray is well resolved at  $V_{\alpha} = 40$  KeV.
- FIG. 3 Decay scheme of  $^{66}\text{Zn}$ , obtained in measurements of  $\gamma$  ray coincidences and yields. Few weak transitions are not presented here: the 2544 KeV  $\gamma$  ray  $^{25}$  which decays from the  $3^{-}$  level at 2836 KeV to the  $2^{+}$  level at 1673 KeV; the 831 KeV  $\gamma$  ray which decays from the 2706 KeV level to the 1873 KeV; the 1276 KeV  $\gamma$  ray which decays from the  $3^{-}$  level at 2765 KeV to the 1039 KeV level. Assignments of spins are based on yield functions, angular distribution analysis and measured  $\beta$  transitions observations within a 5% intensity limit: for the degree of confidence see the text.
- FIG. 4 Comparative decay schemes of  $^{66}_{30}\text{Zn}$  and  $^{68}_{32}\text{Ge}$ , suggesting the idea that the observed levels can be interpreted as neutron shell model states.

Fig 2

X<sup>2</sup> testing was done for the Anderson data. It indicates that the data with our analysis is consistent with the Anderson data.
