**Abstract**

Monte Carlo calculations are performed of the physical and chemical interactions in liquid water by electrons produced during Auger cascades resulting from the decay of various radionuclides. Estimates are also made of the number of direct physical and indirect chemical interactions that would be produced on DNA located near the decay site.

## INTRODUCTION

The biological effects of radionuclides incorporated into mammalian cells are of considerable interest for radiation biology and radiation protection. When radionuclides decay by electron capture or internal conversion an inner atomic shell vacancy is created. The subsequent Auger transitions produce numerous low-energy electrons whose ranges are of subcellular dimensions in tissue-equivalent matter (1,2). When such Auger emitters are localized on or near the DNA of cell nuclei severe biological effects are observed both *in vitro* and *in vivo* (2-4), reminiscent of alpha particles of high linear energy transfer (LET). Indeed, recent experiments with the 5.3-MeV alpha emitter Po-210, intracellularly localized, clearly showed that its lethal effects were essentially the same as those of DNA-incorporated I-125, a prolific Auger emitter (5,6). The relatively high radiotoxicity of Auger emitters has been attributed to the highly localized energy density in the immediate vicinity of their decay sites (7). A more detailed understanding of the equivalent lethality of high-LET alpha particles and DNA-bound Auger emitters may come from track-structure calculations which provide information regarding the number of direct physical interactions and subsequent indirect chemical interactions with the DNA molecule (7,8). Accordingly, track-structure calculations for a variety of medical and environmental radionuclides (Fe-55, In-111, I-125, Pt-193m, Pt-195m) which emit different numbers of Auger electrons are considered in this work and compared with those for alpha particle tracks.

## MONTE CARLO SIMULATION OF AUGER CASCADES

Simulation of the nuclear and atomic events associated with the decay of several Auger-electron-emitting radionuclides was accomplished using Monte Carlo calculational techniques described in detail elsewhere (9,10). Briefly, at any stage of the radionuclide decay, the simulated decay process proceeds randomly by selecting a transition from the set of all allowed transitions for the nuclear as well as atomic configuration at that stage. As the random selections are made, data concerning the emitted radiations are recorded. This random selection process continues until the ground state of the isotope is reached.

Calculations of the energies of Auger electrons produced from a number of decays have been performed for the radionuclides Pt-195m, Pt-193m, I-125, In-111, and Fe-55. The Monte Carlo radiation transport code OREC (8,11-13) has been used to transport the electrons produced during the Auger cascades through liquid water surrounding the decay site and to calculate the physical and chemical interactions produced. In this code, a charged particle and all of its secondary electrons are followed, and the location and type of each inelastic energy loss event is recorded. These physical events occur within  $10^{-15}$ s and produce excited or ionized water molecules and subexcitation electrons. The program then calculates the location and identity of each reactive chemical species that is produced by  $10^{-12}$ s. These chemical species are then followed as they undergo diffusive motion and react with each other or with solute molecules that may be present.

In order to estimate the interactions that might be produced with a DNA molecule, a very simple model has been assumed. A segment of a double-stranded DNA is represented as a right circular cylinder of radius 1 nm

with "sugar" and "base" reactive sites alternating along two helical strands on the surface. Each strand makes one turn in 3.4 nm and has 20 reactive sites per turn. A description of this simple model has been published (8).

For the purposes of this paper two types of interactions with the DNA are considered. During the charged-particle transport the DNA cylinder is treated as though it were water, and if an inelastic energy loss event occurs within the cylinder it is considered to represent a "direct" physical event. No attempt is made to further characterize the event or its consequences. In our calculations there is no limit to the number of these direct events. An "indirect" chemical event is considered to result when a reactive chemical species interacts with a "sugar" or "base" site on the DNA. Only one indirect event can occur with a "sugar" or "base," and hence the maximum number of indirect events is the number of sugars and bases. Although no attempt is made to identify the consequences of these direct or indirect events, it is interesting to compare the relative numbers of such events for various types of radiation.

## RESULTS

Calculations have been performed of the transport of the electrons produced during Auger cascades from decay of the radionuclides Fe-55, In-111, I-125, Pt-193m, and Pt-195m. In order to get a feeling for the relative density of reactive chemical species produced during such cascades, the positions of chemical species from representative decays are plotted in Figure 1. In the four quadrants of the figure the dots represent the initial positions of the reactive chemical species OH,  $\text{H}_3\text{O}^+$ , H, and the hydrated electron  $e^-_{\text{aq}}$  at  $10^{-12}$ s before appreciable diffusion has occurred. In each

case the positions of the sugar and base sites on the two strands of the DNA are also shown. The radionuclide decay site is taken to be on the surface of the cylinder, i.e. 1 nm from the axis. In the lower right quadrant the positions of chemical species produced by a 5.3-MeV alpha particle passing perpendicular to the DNA cylinder are shown. It should be noted that there is significant statistical variation in the Auger cascades. In each case we have taken examples of decays that have produced average numbers of chemical species.

Figure 2 shows the initial distribution of chemical species around the site of the decay of I-125. It shows the number of each of the 4 reactive species in concentric spherical shells of thickness 1 nm centered at the decay site. The hydrated electrons peak somewhat further from the decay site than the other species.

We consider now the number of events that would be produced on DNA as a result of the decay of an Auger emitter. Table 1 shows the number of direct physical and indirect chemical events that would be produced with a segment of DNA by the decay of various Auger emitters located on the surface at the middle of the cylinder, 1 nm from the cylinder axis. For comparison, similar information is shown for 5.3-MeV alpha particles passing perpendicular to the DNA and 1 nm from the axis of the cylinder and also for 5.3-MeV alpha particles emitted isotropically from a point on the surface at the middle of the cylinder. The radionuclide Po-210 emits a 5.3-MeV alpha particle when it decays, and other studies (5,6) have shown that biological effects similar to those from I-125 decay are produced (3).

Figure 3 shows the total number (direct plus indirect) of DNA interactions produced by the decay of various radionuclides as a function of the distance of the decay site from the center of the DNA. Also shown are the

number of DNA interactions from 5.3-MeV alpha particles passing perpendicular to the DNA cylinder at various distances from the axis and from 5.3-MeV alpha particles emitted isotropically from points the same distances from the center of the DNA.

## CONCLUSIONS

The essentially simultaneous emission of electrons from an Auger cascade produces a very high energy density within a few nanometers of the decay site. If the Auger emitter is attached to the DNA it can produce damage to the DNA similar to that of a high-LET charged particle. Although the model for DNA used in this paper is very simplistic, it is interesting to compare the relative numbers of interactions produced by various radiations.

Experimental results discussed elsewhere in this volume (5.6) indicate that the effects of I-125 decay and Po-210 decay producing 5.3-MeV alpha particles have similar biological effects. However, the calculations in this paper indicate that more DNA interactions are produced per decay by the I-125 than the Po-210. Thus one might expect the I-125 to produce more biological effects. However, the alpha particles have a range of ~50 micrometers in unit density matter and will pass entirely through a cell and may interact with the DNA in several places, whereas the high energy density regions from the I-125 decay are confined to only a few nanometers.
