Abstract—An elliptical wiggler has been designed for installation in the Advanced Light Source at the Lawrence Berkeley Laboratory. The design has been optimized for the production of circularly polarized light in the 50 eV to 10 KeV energy range. The device will be 3.4 m long consisting of vertical and horizontal periodic structures. The period length for both is 20 cm. The vertical structure is a hybrid permanent magnet design which produces a peak field of 2.0 T. The horizontal magnetic structure is an iron core electromagnetic design shifted longitudinally by one-quarter period relative to the vertical structure; it has a peak field of 0.095 T. The polarity of the horizontal field can be switched at a rate of up to 1 Hz, which results in a modulation of the chirality of the circularly polarized radiation on-axis. This paper discusses the magnetic design and presents the results of radiation spectra calculations used for determining optimal field parameter settings.

I. INTRODUCTION

Circularly polarized x-rays have become an important tool in the study of the spin state of magnetically ordered materials. An elliptical wiggler, designated as EW20.0, has been designed [1] for installation at the Advanced Light Source (ALS), a third generation synchrotron light source. This will provide a high flux source of elliptically polarized radiation in the 50 eV to 10000 eV energy range. It will be capable of switching between left and right handed polarizations at up to a 1 Hz rate [2]. The main parameters for EW20.0 are summarized in Table I.

Manuscript received June 13, 1995.

This work was supported by the Director, Office of Energy Research, Office of Basic Energy Sciences, Mat. Sci. Div., of the U.S. Dept. of Energy, Contract No. DEAC03-76SF00098.

TABLE I
EW20.0 PARAMETERS

Spectral Range	50 eV - 10 KeV
Period Length	20.0 cm
Number of Periods	14 (vertical) 14½ (horizontal)
Peak Vertical Field	2.0 T
Max. K_y	25.95
Max. Opening Angle	±8.82 mrad
Peak Horizontal Field	0.095 T
Max. K_x	1.5
Max. Opening Angle	±0.51 mrad
Max. Modulation Rate	1 Hz

The device consists of vertical and horizontal magnetic structures. The end and longitudinal views of the magnetic configuration are shown in Figs. 1 and 2, respectively. The vertical magnetic field is produced with a variable gap hybrid permanent magnetic structure; the horizontal field is produced with an iron core electromagnet [2]. This device is conceptually similar to one designed and built by Yamamoto, *et. al.*, at the Photon Factory [3], except, that device uses pure permanent magnet structures for both vertical and horizontal fields, and polarization switching is accomplished by mechanically shifting the horizontal magnetic structure.

Fig. 2. EW20.0 Longitudinal View of Magnetic Structure

II. PRINCIPLE OF OPERATION

The production of circularly polarized light is accomplished by the mixing of the appropriately phased horizontal and vertical polarization components of a photon beam. The electric field produced by the trajectory of an electron passing through a magnetic field is the basis for radiation detected by an observer, and therefore the polarization is directly related to this motion. As an electron passes through a dipole field it bends in the plane perpendicular to the field. As viewed from directly above or below, the motion is circular, with the direction of rotation different for the two views. The apparent motion is linear as viewed from within the plane of motion. If viewed from any other angle, the apparent motion is elliptical. This qualitative behavior of apparent motion carries over to observed states of polarization. Radiation emitted from an electron passing through bend magnet is linearly polarized on axis and elliptically polarized vertically off-axis. Radiation above the axis is polarized with opposite handedness from that below the axis. This provides the basis for the use of dipole magnets as sources of elliptically polarized radiation. However, radiation from a series of wiggler poles, viewed off-axis, results in no net circular polarization, since it consists of radiation from poles of alternating magnetic polarity, and thus alternating chirality. Elliptically polarized flux can, however, be produced on the midplane through the use of a periodic horizontal magnetic field shifted 90° relative to the vertical field. The horizontal field deflects the electron beam vertically so that it passes through the peak vertical field at an angle, which is equivalent to viewing successive poles first from above and then below the axis. This is schematically

illustrated in Fig. 3.

The quality of radiation from an elliptical wiggler is identical to that from a bend magnet. However, it offers the advantage of higher flux due to the multiple poles.

Fig. 3. Elliptical Wiggler Principle of Operation

III. VERTICAL MAGNETIC STRUCTURE

The vertical magnetic field structure consists of a periodic hybrid permanent magnet array with 14 periods. The peak field is 2.0 T; this is varied by opening the gap. The pole material is vanadium permendur. The magnetic excitation is provided by Nd-Fe-B permanent magnet blocks. The poles are tapered in both the transverse and longitudinal directions to minimize saturation. The Nd-Fe-B material is recessed to accommodate the horizontal field poles. The features of the vertical structure are summarized in Table II.

TABLE II
VERTICAL MAGNETIC STRUCTURE

Magnetic Gap	1.4 cm - 22.0 cm
Peak Field	2.0 T - 0.025 T
Maximum Pole Flux Density	2.23 T
Pole Width	10.0 cm
Pole Thickness	4.6 cm
Pole Height	13.4 cm
Nd-Fe-B Operating Point	0.52

The basic building block for the periodic structure is the half-period pole assembly. This unit consists of an aluminum keeper, a pole that is pinned in the keeper and a total of twelve Nd-Fe-B blocks that are bonded to both the

pole and the keeper, six in the front and six in the back. The half-period pole assemblies are mounted on an upper and lower backing beam. The pole assemblies are vertically aligned to within 25 microns with respect to each other on each backing beam.

The design objective for the exit and entrance region is for the average horizontal electron beam orbit through the wiggler to coincide with the central axis. This is achieved by configuring the sequence of pole scalar potentials at the entrance as $0, \frac{1}{4}, -\frac{3}{4}, 1, -1$, etc., and then reversed for the exit. The amount of permanent magnet material in the end regions is adjusted so that this scalar potential sequence is maximally achieved over the full range of magnet gaps.

Tight control of integrated fields imposed by storage ring specifications will be achieved through precise alignment of the magnetic structure and by the specific arrangement of permanent magnet blocks [4]. Final trimming of integral fields will be with end coils to correct the dipole and an array of trim magnets installed in the end to correct higher order field errors [5].

IV. HORIZONTAL MAGNETIC STRUCTURE

The periodic horizontal magnetic field is produced by electromagnets. The structure has the same period length as the vertical structure, but it is shifted by one-quarter period. A total of $14\frac{1}{2}$ periods are included to provide symmetric helicity to the electron orbit at the entrance and exit; this minimizes the production of linearly polarized light at the ends, which would decrease the total fraction of circularly polarized flux. A $0, \frac{1}{4}, -\frac{3}{4}, 1, -1$ scalar potential sequence is maintained at the entrance and exit to maintain the average vertical electron orbit on the axis.

To achieve the 0.095 T peak field, the poles and coils are tucked in between the upper and lower vertical structures. The pole cores are laminated from 0.64 mm thick M36 electrical steel. A system of struts is used for support and adjustment of the poles. The peak field is varied by adjusting the current. The field polarity is switched by changing the current polarity. The coils are energized via a bipolar, regulated power supply that will provide a trapezoidal wave form for frequencies DC to 1 Hz.

The main features of the horizontal magnetic

TABLE III
HORIZONTAL MAGNETIC STRUCTURE

Peak Field	0.0947 T
Max. Pole Flux Density	1.96 T
Conductor	Cu 4 mm SQ \times 2.5 mm ID
Number of Turns/Coil	12
Current	500 A
Total Voltage	135.2 V
Total Power	66.0 KW
Total Flow Rate	25.1 GPM
Coil Temp. Rise	8.8° C

structure are summarized in Table III.

V. RADIATION SPECTRUM

The design objective for an elliptical wiggler is to maximize the flux of circularly polarized photons. However, the spectral output involves a trade-off between flux, F , and the fraction of circularly polarized photons, the degree of circular polarization, P_c . Both of these quantities are functions of the vertical and horizontal field magnitudes. In general, as the ratio of the vertical peak field to the horizontal peak field increases, the total flux increases, but the degree of circular polarization decreases. An optimization must consider a merit function which is some combination of the two quantities. The appropriate merit function for experiments using single event counting to detect asymmetry between the effects of left and right circularly polarized light is the product of the square of the degree of circular polarization and flux. We consider the integral merit function, M , defined as in Eq. 1 [6].

$$M = \int_{\Delta\psi} \int_{\Delta\phi} P_c |P_c| \frac{d^2 F}{d\phi d\psi} d\phi d\psi \quad (1)$$

The horizontal and vertical angles are represented by ϕ and ψ , respectively, and $\Delta\phi$ and $\Delta\psi$ are the respective apertures.

A set of computer codes were developed to calculate the relevant spectral properties at a given photon energy for particular magnetic field parameter values and to optimize the parameter settings for maximum M [7]. The results are summarized in Table IV for an electron energy of 1.5 GeV. The table includes optimum values of B_y , K_x , and vertical half-aperture, $\Delta\psi/2$, and the values of optimized M for a series of photon energies ϵ . The results are for a fixed horizontal aperture, $\Delta\phi$, of ± 2.5 mrad.

TABLE IV
OPTIMIZATION FOR 1.5 GEV

c eV	B_y Tesla	K_x	$\Delta\psi/2$ mrad	$M \times 10^{-13}$ photons/sec
50	0.4	1.5	0.333	3.49
100	0.5	1.49	0.256	3.65
150	0.5	1.30	0.229	3.65
300	0.8	1.13	0.220	3.66
700	1.6	1.07	0.202	3.59
1000	2.0	1.02	0.191	3.38
1500	2.0	0.88	0.165	2.94
3000	2.0	0.67	0.127	1.77
7000	2.0	0.48	0.091	0.415
10000	2.0	0.41	0.079	0.139

The results show several important trends. The optimum value of B_y increases for increasing photon energy, in order to drive the flux intensity distribution to higher energy. Note that the peak field of 2.0 T is reached for a photon energy of 1 KeV. Optimized M is restricted at higher photon energies because of the limit on B_y . Optimum K_x decreases with increasing photon energy. This is because the width of the two polarization components of the radiation become narrower for higher photon energies. The optimum M is limited at the lowest photon energies due to the maximum achievable K_x .

Fig. 4 shows the optimized M for 1.5 GeV and 1.9 GeV electron energies.

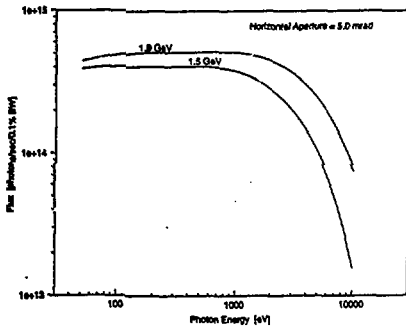

Fig. 4. Optimized M for 1.5 GeV and 1.9 GeV electron energies. Current is 0.4 A and the horizontal aperture is ± 2.5 mrad.
