1. INTRODUCTION

To describe quantitatively how the various fuel design parameters affect the longitudinal ridging behavior of fuel cladding, an empirical correlation that predicts the external pressure corresponding to instantaneous plastic collapse was developed by WCL in 1975 and has been used so far [1]. However, some drawbacks were discovered in the process of assessing the critical longitudinal ridging pressure of CANFLEX fuel. They are summarized as follows:

- (1) As the correlation was mainly fitted to the Pickering type fuel cladding, an erratic prediction of collapse pressure is resulted for the fuel cladding with CANFLEX size thickness and diametral clearance (Figure 13). It does not appear in Pickering type cladding within the application range of the correlation.
- (2) This correlation calculates the pellet-to-diametral clearance (ψ) of collapsed tube using a theoretical equation applicable to an elastic problem. The application of external pressure to the thin wall circular tube may cause an instability failure due to stresses even lower than the elastic limit, and in such a case this formula does not apply [2]. Magnitude of the external pressure (ρ) that causes critical ridging is, of course, greater than the elastic limit. The longitudinal ridging is an example of the instability failure and the application of the equation to the ridging problem is not appropriate.

Therefore, in this study, a new correlation has been developed based on an analytical method to alleviate the probable bias due to the uneven distribution of test specimen parameters and the logical discrepancy in ψ calculation. A static analysis, finite-element (FE) model was developed to simulate the longitudinal ridging of the fuel element with use of the structural analysis computer code ABAQUS [3]. Collapse pressures were calculated for the fifty-one cases for which test results of WCL in 1973 [4] and 1975 [1] are available. Calculation results under-predicted the critical collapse pressure. The trend of under-prediction was corrected in accordance with the measured data of WCL 1973 and 1975 test. Based on the corrected predictions, a new correlation that describes the longitudinal ridging behavior of CANFLEX type fuel elements was derived. It predicts the collapse pressure with an overall average error of - 0.14% and a root-mean-square error of 5.9%, which are smaller than those of the existing correlation that present an overall average error of 0.53% and a root-mean-square error of 6.41%.

2. FE Model Description

2.1 FE Model and Boundary Condition

The FE model of the fuel sheath and the pellet was developed with two-dimensional 6-node triangle element and 4-node quadrilateral element, respectively. As the configuration of the longitudinal ridge shows symmetry, only one half of the element cross-section is modeled as shown in Figure 1. Pellet is placed eccentrically inside the sheath and contacts with the sheath on one side and the ridge is induced to occur on the other side. Pellet is fixed by constraining all degrees of freedom in all nodes on the symmetry line. As for the sheath, all nodes on the symmetry line are restrained in circumferential direction due to its symmetrical configuration and one node on the right extreme is fixed to prevent its rigid body motion.

2.2 Material

Tensile properties at 300°C and 400°C are used for the analysis because the collapse tests in 1973 and 1975 were performed at those temperatures. Fuel sheaths used in the tests consist of various types of materials and they have different mechanical properties from each other. Materials of the fuel sheath and their mechanical properties are summarized in Table 1.

Table 1 Fuel sheath materials and their properties [1]

Component	Material / Test temperature	Young's modulus (MPa)	Yield strength (MPa)	UTS (MPa)	Poisson's ratio
Sheath	Fully-annealed Zr-4 300°C	80,830	134.4	237	0.4
	Fully-annealed Zr-4 400°C	75,230	131	233.6	0.4
	Stress relieved Zr-4 300°C	80,830	186.1	288.7	0.4
	Stress relieved Zr-4 400°C	75,230	158.5	261.1	0.4
	Stress relieved Zr-2.5% Nb 300°C	77,050	207	309.6	0.4
Pellet	Sintered UO ₂	.17E6	250	-	0.3

2.3 Applied loads

External pressure was applied to the fuel sheath and then removed to obtain plastic strain. This process was repeated increasing magnitude of the pressure by 1.724 MPa until the specimen present 0.5% strain because this strain value is always very close to the pressure at which strain very rapidly increases. This is an adaptation to the test procedure, which is described in section 2.1.

3. Application to the 1973 and the 1975 WCL tests

3.1. Description of the tests [1] [4]

In the 1973 and the 1975 WCL tests, test specimens were heated in an autoclave containing argon at low pressure for about 4 to 5 hours to ensure that they are in thermal equilibrium. The autoclave was then pressurized to the test pressure in about two minutes using preheated argon. The pressure was maintained for 100 minutes and it was vented off and the heaters turned off. After being cooled to room temperature, the specimens were profiled at cross-sections using the profilometer. This process was repeated increasing the pressure by 1.724 MPa (250 psi) until the specimen present 0.5% strain. To estimate critical ridging pressure, the strain history of each individual case was plotted by connecting calculated data points with straight line on linear scales of pressure and strain as illustrated in Figure 2. The critical pressure for each specimen was taken as the pressure associated with 0.5% plastic strain because this strain value is always very close to the pressure at which ridge strain very rapidly increases. However, since a linear interpolation may not be a very good approximation to the real ϵ - p behavior for strain values that are not near an observed strain, no critical pressure was estimated for specimens which do not have an observed strain value in the range $.0025 \leq \epsilon \leq .01$. Also, if no strain greater 0.5% was observed, no extrapolations were done to arrive at a critical pressure.

3.2 Correction of the prediction

3.2.1 Critical collapse pressure

Development of an accurate analytical model for critical ridging pressure based wholly on the calculation results is not possible due to the inevitable error in calculation

whether it is big or small. Therefore, the calculation results were corrected in accordance with the measured data of WCL 1973 and 1975 tests.

Figure 3 compares the measured and the predicted critical collapse pressures for fifty-one cases for which test results of WCL 1973 and 1975 are available. Note that different scales are used in the x- and the y-axes. In spite of the trend of under-prediction, this comparison presents that a significant correlation exists between the measurements and the predictions. A least square analysis resulted in a quadratic regression equation and a regression curve as shown in figure 3.

It is obvious that the four points on the upper right side made the best regression line to be quadratic instead of linear. The four points are all associated with the four stress relieved Zr-2.5% Nb (300°C) sheaths, which has the biggest yield strength among the materials used in this analysis. Considering that they have no dimensional peculiarity, it is suspected that its material property is given higher in reference [1] than it really is.

The predicted critical collapse pressures were corrected to the regression equation and compared to the measured collapse pressures in Figure 4. An overall average error of 0.43% was obtained.

Figure 5 shows correction magnitudes as a function of material yield strength. In four material types, magnitude of correction is about 3.6 MPa on average whereas 2.3 MPa is obtained for the stress relieved Zr-2.5% Nb (300°C) sheaths.

3.2.2 Longitudinal ridge curve

Figure 6 shows the predicted and the measured longitudinal ridge curve for fully-annealed Zr-4 fuel element. The measurement data was quoted from the 1982 WCI (Westinghouse Canada Inc.) report [5]. Ovality of the fuel sheath is presented as a function of applied pressure. The rapid increase of ovality is observed at lower pressure in the prediction than in the measurement. It was expected as such because the same trend was observed in the prediction of the critical collapse pressures in section 2.2.1. When the correction magnitude obtained in section 2.2.1 (3.5 MPa for fully-annealed Zr-4 sheath) is added to the predicted ridge curve, the dotted line is obtained. According to the calculation, 0.5% strain is obtained at the ovality of 0.3mm. The corrected prediction and the measurement curves coincide at that ovality. It suggests that quite accurate prediction of critical ridge pressure is obtained using this FE model, even though the predicted ridge curve does not present a strong agreement with the measured curve.

Qualitatively, however, both the predicted and the measured ridge curves have the

same shape. That is, an initial plateau where the tube maintains the same initial out of roundness; an increase in ovality and height of the ridge with increasing pressure, then a new plateau where the saturation of the plastic deformation has been reached and the ridging remains constant with increasing pressure. A small decrease in ridge height at the end of the 2nd plateau is because the ridge becomes shaper as the pressure increases.

4. Data Correlation

Least square analysis is performed based on the corrected predictions. The readily identifiable parameters that are expected to determine the critical collapse pressure (P) for a fuel sheath are outside diameter (d), wall thickness (t), diametral clearance (δ), elastic modulus (E), and yield stress (σ). d, t and δ define the geometry of a fuel element, E characterizes the elastic deformation that can be exhibited by the clad and σ is a measure of how readily plastic deformation occur. Hence the conditions corresponding to collapse instability for fuel elements should be able to expressed as a function of these five parameters.

$$P = f(d, t, \delta, E, \sigma)$$

which can be rewritten by using dimensional analysis in the non-dimensional form:

$$P/E = f(t/d, \delta/t, \sigma/E)$$

In fitting the collapse data to an equation of the above form, the true diametral clearance at test temperature was taken for δ and calculated from :

$$\delta = \Delta + (\text{I.D.}) (T-20) (3.11 \times 10^{-6} + 7.78 \times 10^{-9} (T-20) - \alpha)$$

in which Δ is the as-assembled room temperature diametral clearance. α represents the difference in diametral expansion of sheath and pellet and was taken to be $10^{-5}/^{\circ}\text{C}$ for UO_2 pellet and $1.18 \times 10^{-5}/^{\circ}\text{C}$ for steel pellets [1].

Plots of the critical collapse pressure (P) vs. one of t, δ and σ were drawn for constant values of the other two parameters, as is shown in Figure 6. Please note that inverse of the clearance ($1/\delta$) are used for x-axis in Figure 7(b). Coupled effects of the three parameters on the critical collapse pressure are under investigation and the results will be presented later. Based on these graphs, P/E is represented as linear functions of t/d, t/δ and σ/E for the range of parameter values studied in the collapse calculation.

A least square correlation of the collapse data resulted in the following definition for the external pressure corresponding to instantaneous plastic collapse:

$$P = E/10^6 [-610 + 2841(t/d)^{0.8} + 458(t/\delta)^{0.1}] + 0.03699\sigma$$

$$\delta = \Delta - (\text{I.D.}) (T-20) [\alpha - \{ 3.11 \times 10^{-6} + 7.78 \times 10^{-9}(T-20) \}]$$

Figure 8 compares the predicted critical ridging pressures with the fifty-one measured critical ridging pressures. An overall average error of - 0.14% and a root-mean-square error of 5.9% is presented. These values are smaller than those of the existing correlation that presents an overall average error of 0.53% and a root-mean-square error of 6.41% as shown in Figure 9.

Figure 10 shows deviations in critical ridging pressure prediction of the new correlation for each of the three non-dimensional parameters. These graphs indicate that within the range of test specimen parameters used for its validation ($0.25 \text{ mm} < t < 0.45 \text{ mm}$, $13 \text{ mm} < d < 20 \text{ mm}$, $0 \text{ mm} < \Delta < 0.2 \text{ mm}$, $130 \text{ MPa} < \sigma < 210 \text{ MPa}$) [1], the correlation is unbiased and hence is expected to be a reasonable description for the longitudinal ridging behavior of CANDU type fuel elements.

5. Comparison of the new to the existing correlation

5.1 Form of correlation

For the purpose of comparison with the new correlation, the existing correlation is presented below [1].

$$P = E/10^7 [-1560 + 80600 t/d + 29.1 (d/(100\psi))^2] + 0.0300 \sigma$$

$$\psi = \delta - (d^2 \rho)/(2Et)$$

$$\delta = \Delta - (I.D) (T-20) [\alpha - \{ 3.11 \times 10^{-6} + 7.78 \times 10^{-9} (T-20) \}]$$

ψ , which was considered to be the true pellet-to-clad diametral clearance at the test temperature and pressure, was calculated from equation (5) where $(d^2 \rho)/(2Et)$ is the diameter decrease for an unsupported thin wall circular tube acted upon by the external pressure. However, it should be noted that the application of external pressure to the thin wall circular tube may cause an instability failure due to stresses even lower than the elastic limit, and in such a case this formula do not apply.[Ref.] Magnitude of the external pressure (ρ) that causes critical ridging is, of course, greater than the elastic limit. Therefore, it is not appropriate to calculate the diameter decrease of the fuel sheath subjected to the ridging pressure using equation (5) and the non-dimensional term of ψ should be excluded from the ridging correlation.

In new correlation, the diametral clearance at test temperature (δ) was chosen as a dimensional parameter. As the critical ridging pressure is proportional to the inverse of the clearance ($1/\delta$) as is shown in Figure 7(b), its non-dimensional form became t/δ . Compared to d/δ , t/δ resulted in more accurate correlation because parameter d is inverse proportional to the critical ridging pressure.

5.2 Comparison in collapse pressure prediction

Figure 11 compares predictions of the new and the existing correlation as a function of diametral clearance. Parameter values used are: $\sigma = 167$ MPa, $t = 0.36$ mm, $OD = 13.5$ mm. Dimensions of CANFLEX fuel are used. Please note that 167 MPa for σ is randomly chosen value. When the diametral clearance is 0.13mm, the new correlation gives collapse pressure of 11.03 MPa, which is bigger than that of the existing correlation by 0.57 MPa.

Figure 12 compares predictions of the new and the existing correlation as a function of yield strength. Parameter values used are: $\Delta = 0.13$ mm, $t = 0.36$ mm, $OD = 13.5$ mm. At the yield strength of 174.3 MPa, 11.3 MPa of critical collapse pressure is obtained. It is higher than that of the existing correlation by 0.62 MPa.

Figure 13 compares predictions of the new and the existing correlation as a function of element OD. Parameter values used are: $\sigma = 167$ MPa, $t = 0.36$ mm, $\Delta = 0.13$ mm. New correlation predicted the critical collapse pressure higher than the existing correlation for the range of O.D between 12.2 mm and 17.7 mm.

The existing correlation resulted in an erratic increase in ridging pressure for the sheath larger than 16.6 mm in diameter. As the correlation was mainly fitted to the Pickering type fuel cladding, the quadratic term of the correlation, $(d/(100\psi))^2$ resulted in an inflection of a curve when applied to the fuel cladding with CANFLEX size thickness and diametral clearance. It does not appear in Pickering type cladding within the application range of the correlation.

Figure 14 compares predictions of the new and the existing correlation as a function of sheath thickness. Parameter values used are: $\sigma = 167$ MPa, $OD = 13.5$ mm, $\Delta = 0.13$ mm. New correlation predicted the critical collapse pressure higher than the existing correlation to the thickness of 0.43mm.

6. Efforts for FE Model Improvement and Discussions

Various efforts were made to improve the ABAQUS model for better prediction of the longitudinal ridge behavior of the CANDU fuel sheath that is instantaneously exposed to the external pressure in the CANDU pressure tube. Several modifications of the FE model were tried to accurately predict the longitudinal ridge behavior, but the prediction was not satisfactory as expected:

- 1) Removal of the Initial ovality of the sheath

The average ovality of actual tubes (0.0075 mm Radial ovality) was removed to alleviate under-prediction. It resulted some differences from the previous work. The differences were too small to cover up the trend of under-prediction.

2) Re-evaluation of the material properties

A number of material properties were tested aiming for the ridge to occur at higher pressure. Higher yield strength resulted higher ridge pressure. However, over some level of the strength value, the ridge didn't form at all. And as the strength value became bigger, the ridge strain resulted not to agree with test data.

3) Restraining of the rotation at the ridge end of the sheath

The elements used at the ridge end of the sheath were found not to have rotational degree of freedom at the nodes.

4) Measurement of the calculated ridge strain using the same method as was used in the measurement

It didn't provide better results.

The key difference between the prediction and the measurement are:

- a) The ridge is predicted to form at lower pressure than the actual test results.
- b) The maximum strain value is smaller in the prediction than in the test.

The basis of the difference a) as mentioned above could be reasoned many different ways. However, what I would like to concern at this time is the difference b) as mentioned above. Figure 15 shows the 10,000-minutes creep strain vs. instantaneous collapse strain for the test cases in table 5 of the 1973 WCL test report[1]. The instantaneous ridge strains are much smaller than the 10,000-minutes creep strain as we expect. The deformation increases with time under constant load of external pressure.

However, Figure 16 shows different results from the results shown in Figure 15. Figure 16 shows the same plot for the test cases in table 1, 3 and 4 of the 1973 WCL test report[1]. Test cases performed at lower pressure (less than 12.166 MPa) are not included in this consideration. This figure shows that the instantaneous ridge strains are almost equal to the 10,000-minutes creep strain in average. The procedure adopted in 1973 WCL test that consists of iterative pressurizing and depressurizing of the fuel sheath up to 12.166 MPa resulted in almost the same amount of ridge strain as the 10,000-minutes creep test.

This phenomenon is more conspicuous for the cases tested at higher pressure. Figure 17 shows the 10,000-minutes creep strain vs. instantaneous collapse strain for the tests performed to the pressure step of 13.889 MPa. In this figure, the instantaneous ridge strains are, in average, rather bigger than the 10,000-minutes creep strain.

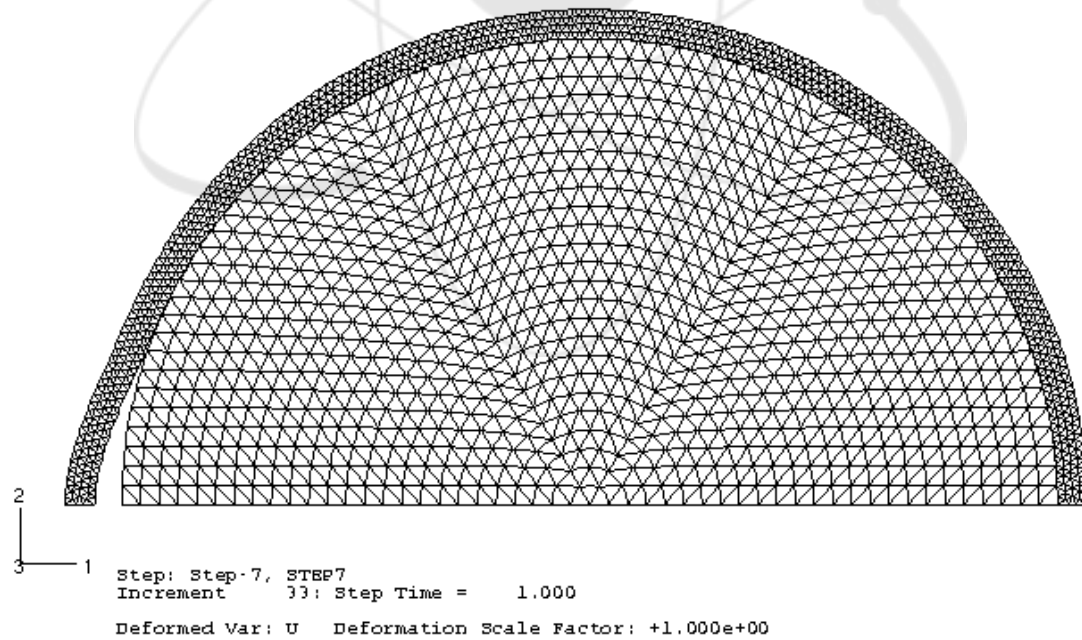

It is not clear why they show different results as shown in Figure 15 and Figures 16 and 17 in spite of the same test procedure. However, the fact that instantaneous collapse shows the same amount of ridge strain as in the 10,000-minutes creep test might be one reason that the simple static analysis cannot provide an accurate prediction for the longitudinal ridge test performed in WCL in 1973. I suggest that an accurate prediction of the longitudinal ridge strain should be left for future work.

<p>CANDU-6 원자로에는 380 개의 핵연료 채널이 있으며, 각 핵연료 채널마다 12 개의 핵연료집합체가 장전된다. 채널내 핵연료로부터 발생하는 열을 제거하기 위해 높은 압력을 가진 중수로 냉각재가 핵연료 집합체열을 통과한다. 핵연료가 원자로에 장전된 직후 이러한 가압 냉각수에 의한 압력의 영향으로 피복관이 그 속에 들어 있는 이산화 우라늄 소결체 표면에 붕괴(Collapse)되어 피복관 축방향을 따라 주름이 형성될 수 있다. 본 연구에서는 컴퓨터 구조해석 소프트웨어인 ABAQUS Ver 6.2 를 사용하여 핵연료 피복관의 축방향 주름 현상을 시뮬레이션하기 위한 유한요소해석 모델을 개발하였다. 개발한 모델을 이용하여 1973 년과 1976 년에 WCL 에서 실험한 51 개 케이스에 대한 붕괴압력을 계산하였다. 유한요소해석으로도 붕괴압력을 정확히 예측할 수는 없었으나, 실험 결과와 중요한 상관관계를 가지는 의미 있는 계산결과를 얻었다.</p>

Abstract						
<p>There are 380 fuel channels in a CANDU-6 reactor, and twelve fuel bundles are loaded into each fuel channel. High-pressure, heavy water coolant passes through the fuel bundle string to remove heat generated from the fuel. Fuel sheath collapses down around the uranium dioxide pellet due to the coolant pressure when the fuel is loaded into the reactor. Longitudinal ridges may form in CANDU fuel element sheaths as a result of sheath collapse onto the pellets. A static analysis, finite-element (FE) model was developed to simulate the longitudinal ridging of the fuel element with use of the structural analysis computer code ABAQUS. Collapse pressures were calculated for the fifty-one cases for which test results of WCL in 1973 and 1975 are available. Calculation results under-predicted the critical collapse pressure but it showed significant relationship against test results.</p>
